8 Different dislocation processes are shown to be operative under high rate loading by impact-induced  
9 shock tests as compared with shockless isentropic compression experiments (ICEs). Under shock  
10 loading, the plastic deformation rate dependence of the flow stress of copper is attributed to  
11 dislocation generation at the propagating shock front, while in shockless ICEs, the rate dependence  
12 is attributed to drag-controlled mobile dislocation movement from within the originally resident  
13 dislocation density. In contrast with shock loading, shockless isentropic compression can lead to  
14 flow stress levels approaching the theoretical yield stress and dislocation velocities approaching the  
15 speed of sound. In iron, extensive shock measurements reported for plate impact tests are explained  
16 in terms of plasticity-control via the nucleation of deformation twins at the propagating shock front.

## 19 I. INTRODUCTION

20 In the 1980s, Follansbee *et al.*<sup>1</sup> reported a strong upturn  
21 in the flow stress of copper, determined at 0.15 strain and  
22 300 K, when tested at the upper end of higher strain rates  
23 achieved in split-Hopkinson pressure bar (SHPB) experi-  
24 ments. The resulting flow stress dependence is shown in Fig.  
25 1. A number of other metals were observed to have similar  
26 upturns in flow stress at strain rates of the order of  $10^4 \text{ s}^{-1}$ .

27 Figure 1 also displays “asymptotes” for the low and high  
28 strain rate dependencies of the activation area for a thermally  
29 activated dislocation model for plastic flow. In the figure, the  
30 asymptotes are labeled with the limiting values of the acti-  
31 vation area  $A^*$  determined from the expression

$$32 \quad A^* = \frac{kT}{b} \left( \frac{\partial \ln \dot{\gamma}}{\partial \tau^*} \right)_T, \quad (1)$$

33 where  $k$  is Boltzmann’s constant,  $T$  is absolute temperature,  
34  $b=0.255 \text{ nm}$  is the dislocation Burgers vector of copper,  $\dot{\gamma}$  is  
35 the shear strain rate, and  $\tau^*$  is the thermal component of  
36 shear stress.

37 For connection of Eq. (1) with the material parameters in  
38 Fig. 1,  $\Delta\tau^* = \Delta\sigma/m$ ,  $\dot{\epsilon} = \dot{\gamma}/m$ , and  $m=3.08$  is the Taylor ori-  
39 entation factor relating single crystal shear stress and strain;  
40 to the corresponding polycrystal effective stress and strain;  
41 see, for example, the thermal activation description for dis-  
42 location dynamics given by Armstrong.<sup>2</sup> In accordance with  
43 that model description of the polycrystal flow stress  $\sigma_e$  at  
44 constant tensile or compressive strain  $\epsilon$ ,

$$45 \quad \sigma_e = m\tau = m(\tau^* + \tau_G + k_s \ell^{-1/2}), \quad (2)$$

46 where  $\tau_G$  is an athermal shear stress that is dependent on the  
47 dislocation density and solute concentration,  $k_s$  is the so-  
48 called microstructural shear stress intensity for overcoming

the grain boundary resistance, and  $\ell$  is the polycrystal grain  
49 diameter.

As will be seen for iron, the slip-determined  $k_s = mk_s$  and  
51 a larger twinning-determined  $k_T$  play important roles in de-  
52 termining the initial yielding responses to shock loading. The  
53 evaluation of Eq. (2) at  $\ell^{-1/2}=0$  is taken to specify the aver-  
54 age dislocation friction stress  $\sigma_0 = m(\tau^* + \tau_G)$ . Also for iron,  
55 the temperature and strain rate dependencies of  $\sigma_e$  are in  $\sigma_0$ .  
56 Otherwise, as noted in Fig. 1 for copper, a relatively large  
57 value of  $A^* \sim 1000b^2$ , corresponding to  $(\Delta\sigma/\Delta \ln \dot{\epsilon})_T$   
58  $\sim 0.8 \text{ MPa}$ , is measured as a typical value for a face-  
59 centered-cubic (fcc) metal tested at conventional tensile or  
60 compressive strain rates, and such measurements are gener-  
61 ally attributed to the thermally activated overcoming of dis-  
62 location intersections during the slip process.

In the present article we account for the strong upturn  
64 shown in Fig. 1 for the copper flow stress measurements by  
65 making connection on a dislocation nucleation basis with  
66

FIG. 1. The flow stress dependence on strain rate of oxygen-free electronic copper at 0.15 strain and 300 K as reported by Follansbee *et al.* (Ref. 1) and fitted with asymptotic activation area  $A^*$  values at the low and high strain rates.

<sup>a)</sup>Electronic mail: rona@umd.edu.

67 other sharply rising, shock-induced, plastic flow stresses  
 68 measured both for copper by Swegle and Grady<sup>3</sup> and for iron  
 69 by Arnold.<sup>4</sup> The upturn in the SHPB measurements of copper  
 70 by Follansbee *et al.*<sup>1</sup> is shown to have provided early evi-  
 71 dence pointing toward the substantially higher shock-  
 72 induced plastic flow stress measurements reported by Swegle  
 73 and Grady.<sup>3</sup> The result is attributed to a changeover from the  
 74 often employed Orowan equation, for relation of  $d\gamma/dt$  and  
 75 the dislocation velocity  $v$  in

$$\frac{d\gamma}{dt} = \rho b v, \quad (3)$$

77 where  $\rho$  is the dislocation density to the alternative disloca-  
 78 tion nucleation equation for  $d\gamma/dt$ , also obtained from  
 79 Orowan<sup>5</sup> as

$$\frac{d\gamma}{dt} = \frac{d\rho}{dt} b \Delta x_d, \quad (4)$$

81 where  $d\rho/dt$  is the rate of nucleation and  $\Delta x_d$  is a small  
 82 distance associated with the nucleated dislocation displace-  
 83 ment.

84 Arnold<sup>4</sup> measured the Hugoniot elastic limit (HEL) pres-  
 85 sure and follow-on jump to a higher plastic flow pressure  
 86 exhibited for plate impact experiments conducted on differ-  
 87 ent grain-sized iron materials. The tests covered a wide range  
 88 of projectile/target thicknesses. Comparison of the results  
 89 with postshock metallographic observations and with the  
 90 previously mentioned grain size dependencies for slip or de-  
 91 formation twinning in iron provides evidence for roles  
 92 played by both deformation responses and transition between  
 93 them in determining reasonably strong, although more so for  
 94 twinning than slip, grain size dependences of the HEL. On  
 95 the other hand, because a substantial shear strain is imposed  
 96 at all points along a propagating shock front with consequent  
 97 relaxation produced in iron by nanoscale twin nucleation, the  
 98 higher shock-induced plastic flow stress will be shown to be  
 99 unaffected by the material grain size.

100 Last but perhaps most interesting is an interpretation put  
 101 forward for recent isentropic compression experiment (ICE)  
 102 results reported for copper by Jarmakani *et al.*<sup>6</sup> No shock is  
 103 produced in the uniform loading of an ICE test, and, there-  
 104 fore, the flow stress levels and dislocation velocities are  
 105 shown to be limited only by the energy dissipation resulting  
 106 from interaction of the moving dislocations with lattice vi-  
 107 brations, that is, the so-called influence of “phonon drag.”  
 108 Consequently, the flow stress may increase to the theoretical  
 109 cohesive limit with velocities approaching the speed of  
 110 sound. Quantitative evaluation of the results of Jarmakani *et*  
 111 *al.*<sup>6</sup> leads to the conclusion that, at the highest peak pressure  
 112 reported of  $\sim 52$  GPa, the plastic flow stress is very near to  
 113 the theoretical limit for copper.

## 114 II. CONVENTIONAL STRAIN RATE, SHPB, AND 115 SHOCK RESULTS

### 116 A. Copper

117 Figure 2 shows over a larger range of stress than in Fig.  
 118 1 a comparison of the SHPB results from both Follansbee *et*  
 119 *al.*<sup>1</sup> and the shock-induced plasticity results of Swegle and

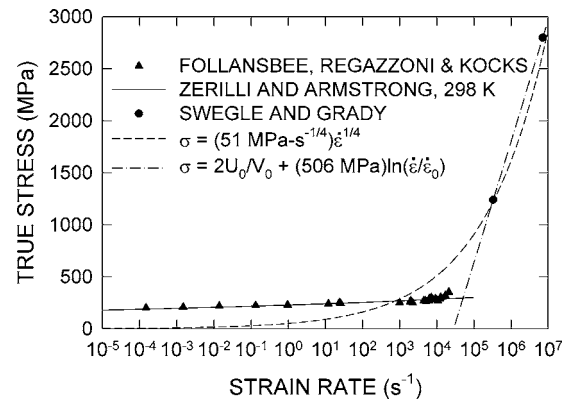

FIG. 2. Flow stress dependence on strain rate reported by Follansbee *et al.* (Ref. 1) (triangles) and shock-induced plasticity results reported by Swegle and Grady (Ref. 3) (circles), compared with ZA thermal activation model, the Swegle–Grady empirical relation, and the thermal activation dislocation nucleation model.

Grady.<sup>3</sup> At the relatively lower stresses shown for the SHPB  
 results, the data follow a thermally activated dislocation me-  
 chanics based relationship proposed by Zerilli and Arm-  
 strong, as updated recently by Zerilli<sup>7</sup> in the fcc form

$$\sigma_\varepsilon = B_0 \varepsilon^{1/2} \exp(-(\beta_0 - \beta_1 \ln \dot{\varepsilon})T) + \sigma_G + k_\varepsilon \varepsilon^{-1/2} \quad (5)$$

in which the experimental constants  $\sigma_G$ ,  $B_0$ ,  $\beta_0$ ,  $\beta_1$ , and  $k_\varepsilon$   
 were determined from other experimental results. The first  
 term on the right-hand side of Eq. (5) is  $\sigma^* = m\tau^*$  in accor-  
 dance with Eq. (2). The empirical relationship

$$\sigma \propto \dot{\varepsilon}^{1/4} \quad (6)$$

proposed by Swegle and Grady<sup>3</sup> is also shown in the figure  
 as the dashed line passing through their pair of shock-  
 induced plasticity measurements. The filled-black-circle  
 stress values are transformed from the measured shock pres-  
 sures  $P$  using the relation

$$\sigma = \frac{1 - 2\nu}{1 - \nu} P, \quad (7)$$

where  $\nu$  is Poisson’s ratio. A value of Poisson’s ratio  $\nu$   
 $= 0.345$  for copper was used.

Armstrong *et al.*<sup>8</sup> proposed that the boundary conditions  
 at the propagating shock front required sequential generation  
 of a nanoscale dislocation structure so that Orowan’s second  
 equation [Eq. (4) above] should be the appropriate relation-  
 ship to employ in a thermal activation model. Further, as  
 seen from the result shown in Fig. 1, a lower limiting value  
 of the area of activation of order of  $\sim b^2$  dimension applies.  
 By incorporation of a lower limiting activation volume  $V_0$ ,  
 then in a thermally activated relationship for  $d\rho/dt$ , the  
 simple relation is obtained

$$\sigma = \frac{2U_0}{V_0} - \frac{2kT}{V_0} \ln \left( \frac{\dot{\varepsilon}_0}{\dot{\varepsilon}} \right) \quad (8)$$

in which  $U_0$  is the Gibbs free energy of activation in the  
 absence of an applied shear stress and the constant  $\dot{\varepsilon}_0$  is a  
 reference upper-limiting strain rate. The flow stress in this  
 case is seen to be linear in  $\ln \dot{\varepsilon}$ .

FIG. 3. HEL and shock-induced plastic flow stresses for ARMCO iron from Arnold (Ref. 4), in comparison with a number of relationships proposed to fit either slip or deformation twinning aspects of the strain rate dependent behaviors.

A comparison in Fig. 3 of the power law ( $\dot{\epsilon}^{1/4}$ ) and linear ( $\ln \dot{\epsilon}$ ) dependence given by Eq. (8) favors the latter description. Nevertheless, model evaluation in this case of the slope of the linear dependence on  $\ln \dot{\epsilon}$  in Eq. (8), with  $V_0 = b^3$  and  $b = 0.248$  nm for slip in bcc iron, gives the dot-dashed line of lower slope that is shown in the figure; the slope is approximately three times lower than the fitted long-dashed line through the combined Arnold<sup>4</sup> and Swegle and Grady<sup>3</sup> data. Armstrong *et al.*<sup>8</sup> accounted for the steeper slope of the shock-induced plasticity results in Fig. 3, corresponding to employment of  $V_0 = (b^3/3)$ , by proposing that the propagating shock front was nucleating a nanoscale structure of deformation twins, with  $V_0 = b_T^2 b$  and  $b_T = 2(a/6)$  [111] for a smallest two-layer twin thickness;<sup>10</sup>  $a$  is the crystal unit cell lattice parameter. Postshock metallographic observations made on Arnold's 80  $\mu\text{m}$  grain size material showed significant deformation twinning for shock pressures greater than  $\sim 3$  GPa, corresponding to  $\sigma > \sim 1.8$  GPa, thus providing evidence for significant residual microscale twinning associated with all of the open circle points.

### III. SLIP/TWINNING TRANSITION AT THE HUGONIOT ELASTIC LIMIT IN IRON

An interesting comparison of predicted slip and deformation twinning stresses also is indicated at the lower level of stress in Fig. 3 for the closed-triangle  $\sigma$  values obtained from Arnold's HEL measurements. In the figure, the horizontal double-dot-dashed line prediction was obtained for the twinning stress  $\sigma_T$  from the equation

$$\sigma_T = \sigma_{T0} + k_T \ell^{-1/2} \quad (9)$$

in which  $\sigma_{T0} = 330$  MPa and  $k_T = 90$  MPa mm<sup>1/2</sup> as determined from other results reported for ARMCO iron and low carbon steel materials,<sup>11</sup> whereas the Zerilli and Armstrong (ZA) curve, that is also shown in the figure, applies for slip-controlled deformation as computed with the bcc-type equation<sup>7</sup>

$$\sigma = B \exp(-\beta T) + A \epsilon^n + \sigma_G + k_y \ell^{-1/2}, \quad (10)$$

in which  $\beta = \beta_0 - \beta_1 \ln \dot{\epsilon}$  and  $\sigma_G$ ,  $B$ ,  $\beta_0$ ,  $\beta_1$ ,  $A$ ,  $n$ , and  $k_y$  were taken from earlier reported experimental constants determined for other results.<sup>12</sup> The indication from the compared relationships and the HEL-transformed (closed-triangle) measurements is that the 80  $\mu\text{m}$  grain size material may have initially yielded by slip but only just so because twinning occurred soon after deformation began, as definitely established via postshock metallographic observations made for the higher open-circle flow stress results.<sup>4</sup>

The competition between slip and deformation twinning in iron and other bcc metals is a well-known consideration in accounting for deformation stress levels measured at low temperatures or high strain rates near to those required for cleavage fracturing. Therefore, it seemed worthwhile to re-examine the total HEL and flow stress measurements reported by Arnold<sup>4</sup> for the 80  $\mu\text{m}$  grain size material, as shown in Fig. 4. The figure legend includes the full range of projectile/target thicknesses that were employed in the tests and shows the dependencies of the four constitutive equations that have been described above;  $\sigma_{SG}$  is for the Swegle

Equation (8) is plotted in Fig. 2, with  $V_0 = A^* b$  taken as  $b^3$  to give  $2kT/V_0 = 506$  MPa at 300 K. The modeled quantity  $2U_0/V_0$  is the theoretical limiting stress for dislocation nucleation and a reasonable order of magnitude estimate of  $\sim 5.8$  GPa was assumed, giving a value of  $\dot{\epsilon}_0 \sim 2.3 \times 10^9$  s<sup>-1</sup>. It is evident from an inspection of Fig. 2 that the data points of Follansbee *et al.*<sup>1</sup> and of Swegle and Grady<sup>3</sup> indicate a smooth transition from thermally activated dislocation motion to thermally activated dislocation generation.

### B. Iron

Much information is available on the shock-induced deformation properties of ARMCO iron (first produced in 1909 by the American Rolling Mill Co., ARMCO ingot iron became the synonym for the purest steel-mill-produced iron, having a purity of more than 99% iron and especially including very low carbon content) that has been employed historically also, as a standard for equation of state studies, particularly relating to the determination by Bancroft *et al.*<sup>9</sup> of a shock pressure of 13.2 GPa for the (bcc) alpha-to-epsilon (hexagonal close packed) phase transformation. Although previous shock-induced deformation results were reported for iron in several pioneering investigations conducted at a single grain size, Arnold<sup>4</sup> investigated the shock-induced deformation properties for ARMCO material with the different average grain diameters of 20, 40, 80, and 400  $\mu\text{m}$ , and, as mentioned, tested in plate impacts covering a large range of projectile and target thicknesses mostly centered on a thickness ratio of 1/2 for added determination of the material spallation properties. In Fig. 3, HEL (closed-triangle) and shock jump plasticity (open-circle) measurements are shown for the 80  $\mu\text{m}$  grain size material that was extensively tested, for example, in this case at an intermediate thickness ratio of 3/6 (in millimeter thicknesses), respectively, for the impacting plate and specimen. Again, the shock pressures have been transformed to effective shear stress measurements according to Eq. (7) but with  $\nu = 0.288$  for iron. Excellent agreement is shown between the open-circle points of Arnold<sup>4</sup> and the pair of filled-circle measurements reported by Swegle and Grady.<sup>3</sup>

FIG. 4. (Color online) A comprehensive listing of shock-induced HEL and plastic flow stresses for ARMCO iron at different projectile/target thicknesses from Arnold (Ref. 4), in comparison with a number of relationships proposed to fit either slip or deformation twinning aspects of the strain rate dependent behaviors.

248 and Grady power law relation and  $\sigma_{AAZ}$  is the thermally  
249 activated dislocation generation relation, Eq. (8).

250 To some extent, the distinctions made reasonably clearly  
251 in Fig. 3 are now blurred by the variations shown among the  
252 greater number of experimental results. On the expanded ab-  
253 scissa scale covering a range of strain rates between  $\sim 6$   
254  $\times 10^3$  and  $\sim 4.5 \times 10^6$   $s^{-1}$ , the lower HEL  $\sigma$  values appear to  
255 follow the computed twinning stress level at first but then  
256 move a little bit upwards at the higher strain rates to the  
257 calculated slip stress dependence that is indicated in Fig. 3.  
258 The same linear in  $\ln \dot{\epsilon}$  dependence of the higher shock-  
259 induced plastic flow stress measurements from Fig. 3 is  
260 drawn in Fig. 4 as the long-dashed line, and the previously  
261 described data are also shown to be buried in the total band  
262 of the higher distributed measurements. Close examination  
263 of the higher distributed stress values shows, at the lower  
264 strain rates, that the shock-induced flow stress jumps to a  
265 relatively constant plasticity level and persists so over an  
266 approximate order-of-magnitude increase in strain rate.  
267 Thereafter, with reasonable variations, the shock-induced  
268 plastic flow stresses follow the linear in  $\ln \dot{\epsilon}$  dependence  
269 previously described with Eq. (8).

#### 270 IV. GRAIN SIZE DEPENDENT HUGONIOT ELASTIC 271 LIMIT

272 Despite the close relationship of the slip and twinning  
273 stress measurements shown in Fig. 4 for the 80  $\mu m$  grain  
274 size material, the competition between the two deformation  
275 mechanisms is strongly influenced by the material grain size,  
276 for example, as evidenced in the comparison of predictions  
277 from Eqs. (9) and (10), and particularly involving the differ-  
278 ent magnitudes of the microstructural stress intensity, for ex-  
279 ample, of  $k_T=90$   $MPa\ mm^{1/2}$  for deformation twinning<sup>11</sup> as  
280 compared with a slip-controlled yield stress value of  $k_y$   
281  $=22$   $MPa\ mm^{1/2}$ ; a lesser value of  $k_\epsilon=5$   $MPa\ mm^{1/2}$  applies  
282 for copper.<sup>11,12</sup>

283 Assessment of the relatively more important grain size  
284 influences on the iron HEL  $\sigma$  values, therefore, is shown next  
285 on a polycrystal reciprocal square root of grain diameter ba-  
286 sis in Fig. 5 for both the slip  $\sigma_S$  and twinning  $\sigma_T$  stress

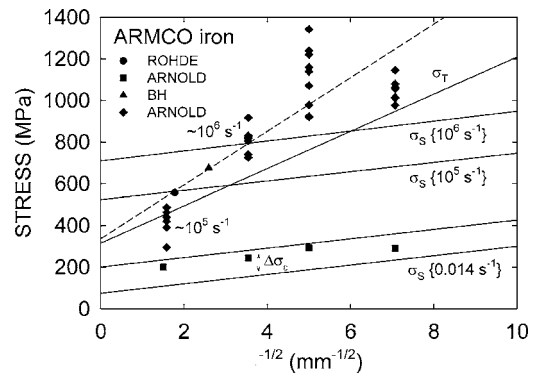

FIG. 5. Preshock hardness and shock flow stress measurements, both from Arnold (Ref. 4), along with shock measurements from Rohde (Ref. 13) and Barker and Hollenbach (Ref. 14) plotted against inverse square root of grain size for both slip and deformation twinning.

dependencies. Individual HEL  $\sigma$  values obtained from earlier  
287 pioneering investigations made by Rohde<sup>13</sup> and by Barker  
288 and Hollenbach<sup>14</sup> are included in the figure. The importance  
289 of a thermally activated  $\tau^*$  in Eqs. (2) and (10) is made clear  
290 by the increasing intercept friction stresses obtained for the  
291  $\sigma_S$  lines evaluated at the differently labeled strain rates. For  
292  $\sigma_T$ , a solid line of correspondingly higher  $k_T$  was obtained  
293 from Eq. (9), and also a dashed line is shown for a possibly  
294 raised  $\sigma_T$  at the higher shock-imposed loading rates. The slip  
295 versus twinning issue for iron had been assessed previously  
296 on this same grain size basis for ARMCO iron SHPB  
297 results<sup>15</sup> and for the current material grain sizes subjected to  
298 Taylor solid cylinder impact tests.<sup>16</sup>  
299

300 Consider first in Fig. 5 the lower filled-square points that  
301 are shown to follow an approximate  $\sigma_S$ -type dependence.  
302 These points were obtained from diamond pyramid hardness  
303 measurements made by Arnold<sup>4</sup> on the different grain size  
304 materials before shocking. For the purpose of Fig. 5, the  
305 individual hardness measurements were divided by a factor  
306 of 3 to represent the material flow stress at a strain value of  
307 0.075. In turn, the lowest  $\sigma_S$  linear dependence shown for a  
308 conventional strain rate of 0.014  $s^{-1}$  was raised by  $\Delta\sigma_\epsilon$   
309  $=A\epsilon^n$  for  $\epsilon=0.075$  by employing the previous iron constants  
310  $A$  and  $n$  mentioned<sup>12</sup> for Eq. (10). Thus, the raised line pass-  
311 ing just above the converted hardness points was obtained.  
312 Reasonable agreement is taken to be shown by the converted  
313 data points and the slip comparison.  
314

315 Next, attention is turned to the higher filled diamond  
316 points for Arnold's converted HEL  $\sigma$  measurements that  
317 were obtained at different grain sizes but at the same 3/6  
318 projectile/target ratio. These data, which are vertically spread  
319 over a range in stress at each grain size, are associated with  
320 different strain rates, also, as indicated at the left-side two  
321 larger grain diameter cases of 400 and 80  $\mu m$  with values of  
322  $\dot{\epsilon} \sim 10^5$  and  $10^6$   $s^{-1}$ . Note that the two higher  $\sigma_S$  lines are at  
323 the same pair of strain rates. Rohde<sup>13</sup> estimated that his filled  
324 circle point was obtained at a strain rate equaling  $10^5$   $s^{-1}$ . In  
325 the Fig. 5 intersection of slip and twinning lines at the higher  
326 strain rate, then, the 80  $\mu m$  grain size material is seen to be  
327 very near to the predicted transition from slip-controlled  
328 plastic flow at smaller grain size and twinning-controlled de-

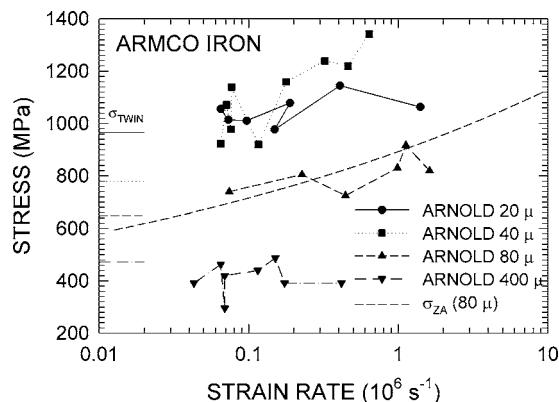

FIG. 6. The strain rate dependence of the HEL yield stresses of ARMCO iron at different grain sizes, from Arnold (Ref. 4), compared with estimated twinning stress levels and, for a grain size of 80  $\mu\text{m}$ , with the bcc ZA slip-type equation (Ref. 7).

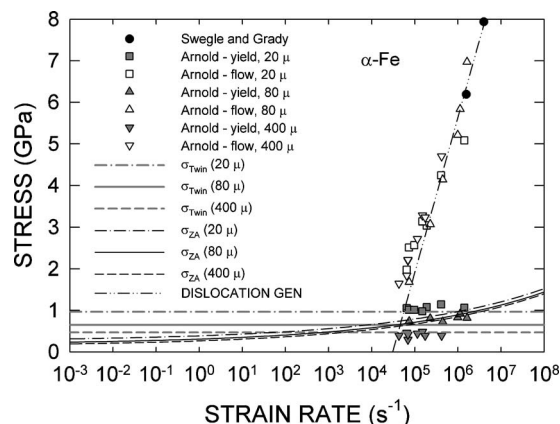

FIG. 7. The HEL and shock stresses for ARMCO iron of different grain sizes, from Arnold (Ref. 4), in comparison with the differently modeled slip, deformation twinning, and twin nucleation stress predictions.

ning (dashed-line) stress dependence may be operable at these greater strain rates. Armstrong and Worthington<sup>17</sup> previously reported a model for deformation twinning that predicted a relatively small strain rate dependence of  $\sigma_T$ .

There is also indication in Fig. 5 of the smaller 40 and 20  $\mu\text{m}$  grain size materials possibly following a  $\sigma_S$  dependence for slip. In this way the measurements would be following the well-known increasing tendency for slip to be rate controlling at finer grain sizes. Figure 6, in showing details of the strain rate dependence, appears at first sight to confirm the indication. In Fig. 6, the abscissa strain rate scale is spread larger to show the HEL  $\sigma$  measurements for the four grain size materials at the respective plastic strain rates determined for the higher shock propagation stresses. The computed twinning stresses from Eq. (9) are marked along the ordinate scale. The relative strain rate independence of the 400  $\mu\text{m}$  grain size material and the level of the stress values compared to the twinning stress marker both are in agreement with the HEL being fully controlled by deformation twinning. The dashed curve through the 80  $\mu\text{m}$  material results is that computed with Eq. (10) by employing the previously determined constants. Agreement is shown with a slip-controlled HEL  $\sigma$  but the determined stress levels, as indicated earlier, occur above the predicted twinning stress level. Here the indication is that the 80  $\mu\text{m}$  material is in the transition region where slip and twinning may be equally preferred but the measured  $\sigma$  values are principally determined by slip. The 40 and 20  $\mu\text{m}$  grain size materials also appear to follow a slip-type strain rate dependence for the HEL  $\sigma$  but their being higher than the predicted twinning stress level cannot be accounted for by the slip-controlled grain size dependence with  $k_y=22 \text{ MPa mm}^{1/2}$ , as shown in Fig. 7.

## V. GRAIN SIZE INDEPENDENT SHOCK-INDUCED PLASTIC FLOW STRESS

Several models have been proposed for dislocation nucleation at a propagating shock front beginning from the pioneering description of shock induced deformations described by Smith.<sup>18-21</sup> A main consideration in determining the need for dislocation (or twin) nucleation is that the large

magnitude of the locally imposed shear strains at all points along a propagating shock front are too large to be relieved by the displacement of the few dislocation line segments contained in, or crossing, the front or by the remote displacement of the resident dislocation density behind the front. The intersection of grain boundaries with the shock front is an even rarer occurrence and thus, the material grain size should not be a significant factor in determining the shock-induced plastic deformation rate. The model consideration is in agreement with the results shown in Fig. 7 for iron of 400, 80, and 20  $\mu\text{m}$  grain size, all tested at 3 to 6 mm projectile/target thicknesses.

In the lower part of Fig. 7, the just-discussed HEL stress values for each grain size are plotted in comparison with both Eqs. (9) and (10) predictions; the 40  $\mu\text{m}$  grain size results are omitted from the figure for clarity. As can be seen at this dimensional scale, except for the 80  $\mu\text{m}$  grain size material results, the emphasis would be on a twinning explanation for the HEL stress and, as mentioned above, the different grain size predictions for slip control are shown to be too small to account for the results. The greater interest in Fig. 7, however, is in the apparent grain size independence of the shock-induced plastic flow stresses at all of the grain sizes. The double-dot-dashed line is the same one drawn in Fig. 3 for the twin nucleation relationship given in Eq. (8). The result provides confirmation of the previously referenced shock model descriptions.

## VI. ISENTROPIC COMPRESSION OF COPPER

As mentioned in Sec. I, the uniform pressure buildup in isentropic compression provides for the possibility of reaching a high plastic flow stress and corresponding high plastic strain rate in shockless loading. Jarmakani *et al.*<sup>6</sup> reported quasi-isentropic compression experiments performed with a two-stage gas gun employing functionally graded impacters applied to [001]-oriented copper crystals sustaining pressures ranging between 17.7 and 51.5 GPa.

Figure 8 shows the effective shear stress measurements, achieved again via transformation with Eq. (7), for test results involving either zero hold time (short) (open-squares) or 10  $\mu\text{s}$ . (long) (filled-square) pressure pulses. The stress

FIG. 8. A comparison for copper of Hopkinson bar, shock, and isentropic compression stresses (Refs. 1, 3, and 6, respectively) as a function of strain rate and fitted with the proposed empirical and model constitutive relationships proposed for the respective strain rate regimes.

FIG. 9. ICE results for copper, after Jarmakani *et al.* (Ref. 6), as a function of strain rate, showing linear stress dependence on strain rate in accordance with model prediction for drag-controlled slip (Ref. 24).

409 values are significantly higher than those in Fig. 2 but, per-  
410 haps surprisingly, the plastic strain rates are lower by one to  
411 two orders of magnitude. For comparison, the previously de-  
412 scribed shock results for copper from Fig. 2 are included in  
413 Fig. 8.

414 Jarmakani *et al.*<sup>6</sup> reported that an amount of deformation  
415 twinning, normally not a major concern in the high rate test-  
416 ing of copper except at the highest loading rates, was de-  
417 tected in post-ICE transmission electron microscope (TEM)  
418 examinations of the specimens tested at the two highest pres-  
419 sures. As evident in Fig. 8, the authors commented that their  
420 results did not follow the Swegle–Grady relationship for  
421 shocking of copper; rather the issue of a slip-twinning tran-  
422 sition was explored via a Preston–Tonks–Wallace (PTW)  
423 constitutive equation<sup>22</sup> to compare estimations of critical  
424 pressures for twinning in both shock and ICE regimes. Rem-  
425 ington *et al.*<sup>23</sup> provided a comparison of similar constitutive  
426 predictions made both by PTW and ZA equations applied to  
427 the high rate deformation of tantalum material; see their Fig.  
428 1(b). Also, it is notable that the Jarmakani *et al.*<sup>6</sup> TEM ob-  
429 servations were interpreted to show production of fewer dis-  
430 locations in the post-ICE test specimens.

431 In Fig. 9, rather than consideration of a transition from  
432 slip to twinning, focus is directed to the experimental linear  
433 dependence of  $\sigma$  on the direct strain rate. In a previous  
434 report,<sup>24</sup> it was proposed that the ICE and shock tests are  
435 fundamentally different in that Orowan's Eq. (4) for disloca-  
436 tion generation is operative for the shock case, as discussed  
437 above for both copper and iron results, but under the shock-  
438 less loading condition in isentropic compression, the strain  
439 rate is carried by the movement of mobile dislocations acti-  
440 vated within the resident dislocation density described by  
441 Orowan's Eq. (3). The additional complication in this case is  
442 that with a dislocation density of, say,  $\sim 10^7 \text{ cm}^{-2}$  and  $b$   
443  $= 0.255 \text{ nm}$ , the average dislocation velocity at a shear strain  
444 rate of  $\sim 5 \times 10^4 \text{ s}^{-1}$  would be  $\sim 2000 \text{ m/s}$ , compared to an  
445 elastic shear wave speed of  $\sim 2900 \text{ m/s}$ . The estimated dis-  
446 location velocity is too large to neglect the drag force on  
447 dislocations during their movement between thermal ob-  
448 stacles in the normal thermal activation description.

449 Previously, Zerilli and Armstrong<sup>25</sup> incorporated disloca-

tion drag into a thermal activation model based on Orowan's  
Eq. (3) as part of an investigation leading to added drag  
resistance being a discounted option for explaining the up-  
turn in the SHPB flow stresses shown in Fig. 1. From the  
previous investigation, the equation for a thermal component  
of effective shear stress including drag resistance is

$$\sigma^* = B \exp(-\beta T) \left( 1 - \frac{c\dot{\epsilon}}{\beta_1 \sigma^*} \right)^{-\beta_1 T}, \quad (11)$$

where

$$c = c_0 m^2 \beta_1 / \rho b^2 \quad (12)$$

is a constant and  $c_0$  is the drag coefficient defined by the  
equation

$$b\tau = c_0 v, \quad (13)$$

where  $b\tau$  is the force per unit length of dislocation line.  
Equation (11) is an implicit equation for  $\sigma^*$ . In the high  
strain rate limit, the solution reduces to

$$\sigma^* = \frac{c}{\beta_1} \dot{\epsilon}. \quad (14)$$

A value of  $c/\beta_1 = c_0 m^2 / \rho b^2 \approx 0.4 \text{ MPa s}$  is shown in Fig. 8  
to fit the Jarmakani *et al.*<sup>6</sup> data. The exact solution for Eq.  
(11) is shown as the dash-double-dot line in both Figs. 8 and  
9. In the expanded scale of Fig. 9, the linear relation, Eq.  
(14), is plotted as the light solid line, which, in the region of  
strain rates of the experimental data, is seen to be nearly  
indistinguishable from the exact solution.

Determination of the drag coefficient from the linear  
slope in Fig. 9 requires an estimation of the dislocation den-  
sity, which can be made from Orowan's Eq. (3). In term of  
the effective strain rate, Eq. (3) becomes

$$\dot{\epsilon} = \frac{\rho b}{m} v. \quad (15)$$

The upper limit to the dislocation velocity is the shear wave  
speed. Taking the value of shear wave speed for copper to be  
2900 m/s and a strain rate value  $\dot{\epsilon} \approx 7 \times 10^4 \text{ s}^{-1}$  correspond-

ing to the highest strain rate data point of Jarmakani *et al.*,<sup>6</sup> then, from Eq. (15), a value of  $\rho \approx 2.9 \times 10^7 \text{ cm}^{-2}$  is determined. The value is low but not unreasonable for the mobile dislocation density. With this value of  $\rho$ , using Eq. (12), the estimated drag coefficient  $c_0 \approx 8 \times 10^{-4} \text{ Pa s}$ .

Lastly, there is the issue of comparing the foregoing drag coefficient to experimental values that have been reported previously for the movement of individual dislocations, generally, at orders of magnitude lower stress levels. Jassby and Vreeland<sup>26</sup> reported such drag coefficient measurements for copper to be in the range of  $1 \times 10^{-5}$  to  $8 \times 10^{-5} \text{ Pa s}$ . Their own measurement gave a value of  $1.7 \times 10^{-5} \text{ Pa s}$  at 296 K. The value calculated here exceeds the reported values by at least an order of magnitude. However it is well known that as the elastic shear wave velocity is approached, the dislocation drag coefficient should increase without bound, becoming infinite at the shear wave speed (for example, see De Hosson *et al.*<sup>27</sup>). Thus, the present result is quite consistent with the idea that, at the highest strain rates achieved by Jarmakani *et al.*,<sup>6</sup> mobile dislocation velocities are approaching the shear wave speed with flow stresses due to drag approaching the theoretical yield stress limit for velocity control.

## VII. CONCLUSION

The strain rate dependence of the flow stress of copper has been tracked over a very large range from  $\sim 10^{-4}$  to nearly  $10^7 \text{ s}^{-1}$ . Along the way, a number of different dislocation mechanics-based mechanisms have been associated with the measurements, for example, of dislocation intersections at conventional tension or compression measurements, of transition at the high end of SHPB measurements to dislocation nucleation that is shown to be rate controlling for impact-induced shock wave propagation, and lastly, of ICE-type drag-controlled very high dislocation velocities being operative at exceptionally high stresses.

For the higher ICE results displayed in Fig. 8, deviations from the normal thermal activation flow stress due to drag begin appearing at strain rates as low as  $500 \text{ s}^{-1}$  and become significant by  $1000 \text{ s}^{-1}$ . On the other hand, the lower stress dislocation generation control shown for the shock cases in Figs. 2–7 tends to limit the increase in flow stress to smaller values characteristic of an increased dislocation density and defers any possible influence of drag to higher imposed strain rates.

Finally, the strain rate dependence of the HEL yield stress of iron of different grain sizes tested in plate impact tests has been accounted for in terms of competition between alternative grain-size-dependent slip and twinning deforma-

tion responses but followed by grain-size-independent shock-induced plasticity controlled by the nucleation of deformation twins. The thermal activation areas determined from the strain rate sensitivity  $(\Delta\sigma/\Delta \ln \dot{\epsilon})_T$ , as evaluated for twin nucleation in ARMCO iron and for slip nucleation in shocked copper, are importantly attributed to needed mechanisms of relief of the very large strains imposed at all points along a propagating shock front.
