The hardness properties of materials are tracked from early history until the present time. Emphasis is placed on the hardness test being a useful probe for determining the local elastic, plastic, and cracking properties of single crystal, polycrystalline, polyphase, or amorphous materials. Beginning from connection made between individual hardness pressure measurements and the conventional stress-strain properties of polycrystalline materials, the newer consideration is described of directly specifying a hardness-type stress-strain relationship based on a continuous loading curve, particularly, as obtained with a spherical indenter. Such effort has received impetus from order-of-magnitude improvements in load and displacement measuring capabilities that are demonstrated for nanoindentation testing. Details of metrology assessments involved in various types of hardness tests are reviewed. A compilation of measurements is presented for the separate aspects of Hertzian elastic, dislocation-mechanics-based plasticity, and indentation-fracture-mechanics-based cracking behaviors of materials, including elastic and plastic deformation rate effects. A number of test applications are reviewed, most notably involving the hardness of thin film materials and coatings.

## 1. Introduction

The hardness test involves a shaped indenter tip, a specimen surface, and a means of applying force and/or displacement associated with initiating contact and either intended blunting of the indenter or penetration of the specimen surface, then to be followed by unloading separation of the indenter and specimen. Walley has provided an historical context for the hardness test [1]. Our purpose here is to carry on by providing background to a number of developments on the subject and to reviewing researches on the topic until the present time. We begin by noting that the subjects of hardness and hardness testing are far too wide-ranging for complete coverage to be attempted in any single review article. Evidence for the preceding statement is provided by inclusion of a substantial list of books on the combined topics along with an additional listing of a number of review articles and conference proceedings on focused sub-topics. In the current report, particular emphasis is given to a number of issues:

- (1) the governing equations for elastic, plastic, and cracking behaviors at hardness indentations;
- (2) comparison of hardness and conventional stress-strain descriptions, leading to the relatively new consideration of a direct hardness-based stress-strain curve;

---

\*Invited article for the International Journal of Modern Physics B; submitted 8 January, 2013.

- (3) metrological aspects of hardness testing, especially as relating to the recent explosion of activity on nanoindentation testing;
- (4) selected descriptions of results reported on each of the subjects of
  - (a) elastic hardness and rebound measurements,
  - (b) the onset of indentation plasticity, particularly as described in terms of dislocation deformations and atomic modeling results, and
  - (c) the occurrence of cracking and indentation fracture mechanics measurements;
- (5) hardness measurements on
  - (a) crystals and anisotropy of slip deformations including dislocation-initiated cracking at slip band intersections,
  - (b) Hall-Petch aspects of polycrystal and composite polyphase deformations, and
  - (c) amorphous material shear banding and cracking; and
- (6) selected applications of hardness testing, especially, to thin films and coatings.

### 1.1. Historical aspects

We begin with mention of an early 17<sup>th</sup> century contribution by Hooke who signaled the beginning of the microscopic examination of materials via, at relatively low optical magnification, observing the rounded end of a needle point [2]. It waited until the 19<sup>th</sup> century for the microscopic examination of metals to gain significantly greater impetus from the seminal work by Sorby [3] while the idea of making use of the “needle point” to reveal in any manner the lattice structure of a metal or to be a materials probe was only to be significantly brought forward in the 20<sup>th</sup> century. For example, Mueller presented a review of field ion microscopy observations of the lattice structure of crystal atoms and imperfections able to be made with atomic scale resolutions for needle points of ~5 to ~150 nm tip radii for tungsten emitters [4]. This was to be followed by a news note on a new technique of scanning tunneling microscopy that employed a sharpened tungsten tip positioned ~5 nm above a material conducting surface in order to reveal its topography at atomic scale resolution; these researchers being interested themselves in the use of a sharp indenter tip for measuring the ultimate hardness of a material with a smallest tipped indenter [5]. In 1986, Binnig and Rohrer shared, with Ernst Ruska for his earlier work on electron optics and designing the first electron microscope, the Nobel Prize in Physics for inventing the Scanning Tunneling Microscope (Atomic Force Microscope) based on the tunneling of electrons between the sharp tip of a probe and a specimen surface [6].

Current probe-type research activities are reported at sub-nanometer dimensions for AFM measurements of an exaggerated difference in chemical bond order of 0.07 nm due to interaction at a separation of 0.34 nm between a tip-attached CO molecule and atomic displacements on a C60

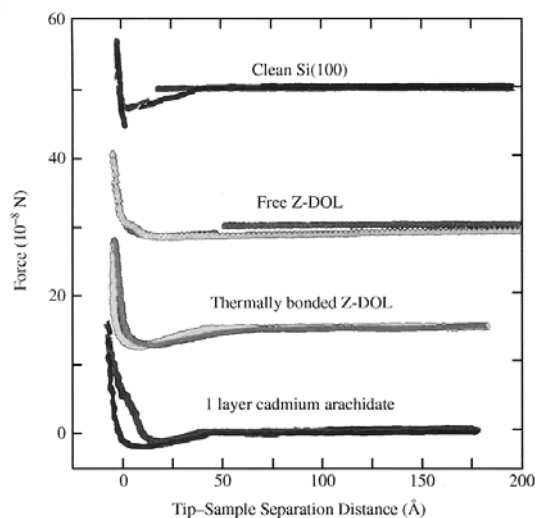

Fig.1. Force on AFM tips associated with contact and withdrawal from different surface layers [10].

fullerene surface structure [7]. The dimensional resolution compares with STM images of 0.06 nm dislocation slip-step heights revealed on an indented (001) gold crystal surface [8]. Blackman, Mate and Philpott [9] have reported on application of the AFM, as developed by Binnig and colleagues, to study discontinuous plastic deformation “pops” during tungsten tip loading of (soft solid) polymeric cadmium arachidate single and multi-atomic layer films deposited onto a silicon single crystal surface.

In a follow-up report containing Fig. 1 for a number of vertically offset pairs of curves for AFM interaction with different types of lubricant films on a silicon surface, Mate [10] describes the upper broken curve for the AFM tungsten tip approaching the silicon surface until an attractive (van der Waals) force produces the indicated sudden jump to establish contact at  $\sim 2.0$  nm distance between a meniscus of contaminant molecules on the tip and the silicon crystal surface and then, for the adjacent lower curve, the contaminated tip must be withdrawn over a larger distance to achieve a total break-free condition from the meniscus. The lowest pair of curves was obtained in meniscus-free condition for the tip and a single layer of soft solid cadmium arachidate material in which case evidence is shown of the material layer of  $\sim 2.8$  nm thickness having been indented to a depth of  $\sim 2.0$  nm. Such research effort has been directed to achieving a better understanding of lubrication and friction for designing and manufacturing electronic disk drives at the scale of atomic and molecular dimensions. The modern researches have counterpart hardness connection in pioneering hardness-based researches by Tabor and Winterton [11] on measurement of van der Waals forces between cylindrically-curved mica sheets at  $\sim 5$  to  $\sim 30$  nm separations and on wear-related measurement of adhesion forces by Pashley, Pethica and Tabor [12].

Gane and Cox [13] obtained the scanning electron microscope (SEM) image of Fig. 2 in a study of indentation sizes made as small as 200 nm with a field-ion-microscope tungsten indenter applied to a gold crystal surface. The measurements made at small loads nevertheless led to clear determination of an indentation size effect (ISE) for the mean hardness pressure over a range in indentation sizes from  $\sim 0.5$  mm down to  $\sim 0.2$  micrometers through showing a substantial increase at smaller size. The measurements were achieved with a series of spherical indenters of different diameters so as to keep a constant ratio of indentation-diameter-to-ball-diameter, ( $d/D$ ). The ISE was attributed to an increase in stress necessary to operate dislocation sources.

Fig. 2. SEM picture of tungsten indentation in gold [13].

Follow-up research was done on the same topic of electron microscope examination of the indentation process by Gane [14]. Experiments were performed both in the SEM and in the transmission electron microscope (TEM). A smallest load of  $\sim 10^{-6}$  N was applied. Very interestingly, Gane included study of the compression of  $\sim 2$  mm and  $\sim 0.5$  micrometer diameter spherical gold crystals with finding a substantial increase in hardness for the smaller particles. The additional case of blunting of a soft (aluminum)

indenter tip against a hard surface was included. The initial dislocations involved in the blunting were observed to escape from the nearby indenter surface but were internally built-up at later stages of blunting. The latter case of intended indenter blunting relates to a much later report, made at very different hardness pressures and dimensional scales, of a hardened steel ball being blunted in the course of producing ring cracking in an industrial diamond material [15].

Fig. 3. TEM shadow micrographs of blunting of a gold indenter tip pressed against a hard surface and including contact pressure estimations: (a) pre-contact; (b) after a contact pressure of ~932 MPa; (c) after ~785 MPa; and, (d) after ~687 MPa; note the occurrence of a decreasing pressure at greater blunting indicative of an indentation size effect [13, 14].

## 1.2. Analysis

During the latter part of the 19<sup>th</sup> century and with a burst of activity at the beginning of the 20<sup>th</sup> century, a number of research reports centered on a combination of interests, first, in the new subject of contact mechanics and, secondly, of equal attention from industry in both reporting and interpreting indentation hardness test results. Here, we first concern ourselves with the breakthrough analysis of Hertz [16, 17] in establishing the modern mechanics of indentation hardness testing. Hueber [18] later reported on the full elastic stress state beneath an elastic contact. And Hencky [19] provided pioneering insight on the nature of the deformation pattern produced by a plastic indentation.

### 1.2.1. Hertz equations

The Hertzian analysis provides a mechanics basis for the description of stress as the mean pressure acting on an indenter contact area and a definition of strain either relating to the indenter penetration depth or area of contact. The pressure required for elastic penetration of a ball indentation is given by

$$P = (4/3)[\{(1 - \nu^2)/E\}_B + \{(1 - \nu^2)/E\}_S]^{-1}(D/2)^{1/2}h_e^{3/2} = (4/3)E_r(D/2)^{1/2}h_e^{3/2}. \quad (1)$$

In Eq. (1),  $P$  is the applied load, the  $\nu$  and  $E$  terms are for the ball and specimen, respectively,  $D$  is the ball diameter,  $E_r$  is the effective elastic modulus for the indentation and  $h_e$  is the depth of elastic displacement (see Fig. 14 for elastic nanoindentation of an alumina crystal). The indentation depth,  $h_e$ , is related to the contact diameter,  $d_c$ , by

$$h_e = d_c^2/2D. \quad (2)$$

A cubic dependence of  $P$  on  $d$  was experimentally verified by Hertz [16] for elastic displacement measurements made by pressing a glass lens onto a flat glass plate. Thus, Eq. (1) may be written in terms of dependence on  $d_c$  as

$$P = (1/3) (E_r/D) d_c^3. \quad (3)$$

Equation (3) is to be utilized later in describing the elastic, plastic, and cracking behavior of silicon. The mean pressure achieved in elastic contact is

$$\sigma_{He} = P/(\pi d_e^2/4) = P/(\pi h_e D/2). \quad (4)$$

The elastic hardness dependence on  $d_e$  and on  $h_e$  is thus obtained as

$$\sigma_{He} = (4/3\pi)E_r(d_e/D) = (4/3\pi)E_r(2h_e/D)^{1/2}. \quad (5)$$

The  $(d_e/D)$  dependence in Eq. (5) suggests itself as a convenient measure of the hardness strain

$$\varepsilon_H = (d/D). \quad (6)$$

### 1.2.2. The plastic hardness stress and hardness-determined cracking stress

In similar manner to Eq. (4), the plastic hardness stress is specified as

$$\sigma_{Hp} = P/(\pi d_p^2/4). \quad (7)$$

In Eq. (7),  $d_p$  is the surface-projected indentation diameter measured generally after unloading and is generally unchanged from the value under load as the unloading displacement for a fully plastic indentation is accounted for by raising and flattening of the bottom of the plastic indentation. For a rigid ball indentation,

$$d_p = 2[h_p(D - h_p)]^{1/2}. \quad (8)$$

Thus by substitution, the plastic hardness stress,  $\sigma_H$ , can be expressed as

$$\sigma_{Hp} = P/\pi[h_p(D - h_p)] \approx P/\pi h_p D. \quad (9)$$

For indentation-produced cracking, a fracture mechanics-based relationship for the load dependence on crack size of a radial, penny-shaped, or median crack was obtained in a seminal analysis reported by Frank and Lawn [20]. One expression for the load dependence of cracking is expressed in Eq. (10) as

$$P = (1/.015) [(d_C/d_V - 1)^{1/2} (H/E_S)^{2/3} K_C d_C^{3/2} \approx (1/\chi_C) K_C d_C^{3/2}. \quad (10)$$

Equation (10) was developed by Laugier [21] for a radial crack of tip-to-tip length,  $d_C$ , at a diamond pyramid (Vickers) indentation of hardness,  $H$ , obtained for a residual plastic diagonal length,  $d_V$ , in a material with elastic modulus,  $E_S$ , and indentation fracture mechanics value,  $K_C$ . Elban, Sheen and Sherwood [22] evaluated  $K_C$  for measurements made on sucrose crystals. Atkinson, Martinez-Esnaola and Elizalde [23] have described the obtainment of  $K_C$  values for various crack geometries. Puttick, Smith and Miller [24] reported development of a plasticity-based median crack geometry somewhat similar to that reported by Atkinson *et al.* for indentation of a silicon crystal and with connection to updated fracture mechanics results on PMMA reported by Lach, Gyurova and Grellman [25]. Lach *et al.* utilized the method of Laugier to determine indentation fracture mechanics toughness values in agreement with conventionally determined values. Atkinson *et al.* provide a discussion and appendices on comparison of Hueber's description of the Hertzian-type and Boussinesq (point loading [26]) analyses further developed by Lawn and co-workers for median crack initiations. In another analysis, Eq. (11) was developed by Lawn [27] for a linear elastic stress dependence on crack size as

$$\sigma_C = [4E_S\gamma/\pi(1 - \nu_S^2)(\kappa_1^2 + \kappa_2^2)]^{1/2} d_C^{-1/2} = K_C [2/\pi(\kappa_1^2 + \kappa_2^2)^{1/2}] d_C^{-1/2}. \quad (11)$$

In Eq. (11),  $\gamma$  is the crack surface energy and  $(\kappa_1^2 + \kappa_2^2)^{1/2} = 2.5 \times 10^{-5}$ . Thus, Eq. (11) was reported as a Griffith-like elastic hardness-based cracking stress and will be employed in the following descriptions of a number of hardness-based stress – strain curves; see Figs. 7, 11 and 15. On an effective  $(d/D)$  basis for the

hardness strain, Eq. (11) is modified to confirm the experimental observation of a lowered cracking stress for a larger ball diameter.

On the industrial side of practically specifying the plastic hardness properties of materials, Brinell [28] reported in a series of articles a hardness pressure that he defined as the load divided by the surface area of a spherically-shaped cap taken for the shape of a residual plastic indentation. Wahlberg [29] elaborated on Brinell's description. Walley has tracked these and other research accomplishments of the era in detail [1]. In a follow-up to Brinell, Meyer [30] provided also in a series of articles a more simple description of specifying the hardness pressure by employing the projected surface diameter,  $d_p$ , of a plastic indentation. The same measure is given above for the elastic contact in Eq. (7) and is often usefully approximated in Eq. (9) by making use of Eq. (8). Ludwik [31] is often given credit too for connection of hardness pressure and the stress – strain properties of materials especially in relation to describing the conventional plastic stress – strain relation in terms of a logarithmic strain dependence of the plastic flow stress. An important discussion of the hardness measurements that were being made at the time was given by Turner based on his own considerable experience with the topic [32].

### 1.3. Previous books, reviews, proceedings

The hardness properties of materials as related to modern understanding were first written about in a number of books published after the beginning of the 20<sup>th</sup> century and in continuing publications until the present time.

A list is provided in the Appendix of research articles additional to those directly commented-on in the text and is presented in the same order of topics and sub-topics.

## 2. Stress – strain behavior

In many early researches, hardness measurements were made in association with separate determinations of force – elongation or compression curves leading to the development of now-conventional hardness-based stress – strain curves.

### 2.1. Connection to compression/tension testing

A natural outcome of the combination of the many experimental results reported on tensile testing as compared with hardness testing of metals and alloys leading up to the first half of the 20<sup>th</sup> century was to investigate the relation between the results obtained from the two testing procedures. Interest in the two property measurements were not far apart in time. Examples of earlier researches leading to a description of stress – strain results were given by Ewing [33] and by Unwin [34], in the latter case drawing attention to the distinction between gradual onset of plasticity for face-centered cubic (fcc) copper as compared with a pronounced yield point behavior for body-centered cubic (bcc) mild steel. Unwin followed this referenced report with an article on development of a new indentation test [35]. Then later, several significant advances in understanding the nature of the plastic hardness property and its connection with the unidirectional stress – strain properties of metals began anew with the researches of Bishop, Hill and Mott [36], to be followed by Tabor [37, 38] and by Krupkowski and Truszkowski [39].

Fig. 4. Tabor compilation of steel ball indentations in copper, after Krupkowski [37].

An early result included in Tabor's 1948 article [37] is shown in Fig. 4 that is credited to a 1931 report by Krupkowski. Note in the figure that the ordinate axis is expressed in terms of  $F/d^2$ , perhaps in deference to Meyer's work, and also that a dashed line has been newly added near to the ordinate axis of the graph in accordance with prediction of Eq. (5) for the Hertzian elastic loading dependence.

The agreement between the plastic hardness results obtained at different ball sizes and comparison of the shape of the hardness-based stress - strain curve with that observed in the tensile deformation of copper served to further justify taking  $(d/D)$  as a measure of the hardness strain, this also being consistent with Meyer's above-referenced articles reporting on hardness stress - strain results. The early work of Tabor and others preceding him led to the following relationship

$$\sigma_{Hp} = C\sigma_{\epsilon} \quad (12)$$

In Eq. (12), the constant  $C$  was taken to be in the range of  $2.8 \leq C \leq 3.0$ , and  $\sigma_{\epsilon}$  was taken as the ultimate tensile stress. The relationship between the tensile strain,  $\epsilon$ , and the hardness strain,  $\epsilon_H$ , was estimated as

$$\epsilon \approx (1/5) \epsilon_H = (1/5)(d/D). \quad (13)$$

Fig. 5. Tensile stress - hardness comparison for ASTM A710 steel [45].

Support for Tabor's description of the hardness stress – strain behavior was provided by Hill, Storakers and Zdenek who re-examined on a continuum plasticity basis the Brinell model for determining hardness [40]. Specific agreement was provided with Tabor's specification of  $C = 2.8$  in Eq. (12) and for achieving In Fig. 5, the steep line is the elastic loading line,  $\sigma = E\epsilon$ , for the steel material tensile result and containing an inverted triangle point on the line for the maximum tensile stress elastically supported according to fit of the Hertz equation to the initial loading achieved with a 1.875 mm diameter hardened steel ball. The plastic hardness measurements,  $\sigma_{Hp}$ , were converted to plastic flow stress values,  $\sigma_e$ , according to the relationship  $\sigma_e = \sigma_{Hp}/2.8$ . The two filled square points were obtained from the tensile loading curve as an initial proof stress value and final true ductile fracture stress. The open circle measurements were obtained from individual (Rockwell) hardness test measurements. The remaining inverted triangle points were obtained from the terminal load values determined for individual continuous loading curve tests.

Connection also has been made between the temperature dependence of hardness measurements and a similar dependence for the flow stress of materials developed in pioneering work by Westbrook [46]. Gilman provides a succinct review on so-called "hot hardness" [47]. There is relation by Gilman to work on the concentration dependence of hardness for halide crystals by Chin, Uitert, Green and Zydzik [48] and to the temperature dependence of the hardness of germanium and silicon. Recent measurements have been reported on silicon, also with determination of a high pressure transformation to a metallic phase whose presence was confirmed by Raman microanalysis [49]. The general consideration of a temperature dependence of the hardness connects also with influence of an indentation rate dependence that is treated here as a separate topic in Section 5. Deformation Rate Effects.

## 2.2. Direct determination of the hardness stress – strain curve

The obtainment of continuous indentation loading curves led to the notion of directly measuring the hardness pressure of a material as a function of the elastic/plastic contact area that could be obtained as a function of the indentation depth [50]. Fig. 6 shows a macro-scale continuous indentation loading result obtained on an NaCl crystal with a 6.35 mm steel ball and displacement measured autographically by crosshead movement while force was measured with a compression load cell mounted on a relatively stiff testing system [51]. On initial loading, the elastic displacement was measured to be in agreement with the Hertz prediction as indicated by the dashed  $h_e$  curve from Eq. (1), with  $P = W$ , and was followed by the type of "pop-in" plastic deformation to be shown later in the present article as being much more prominent in current nanoindentation test results. Shift of the dashed  $h_e$  curve to the unloading result in the figure showed that the unloading curve designated,  $h_u$ , when corrected for the machine compliance,  $\Delta h_m$ , followed

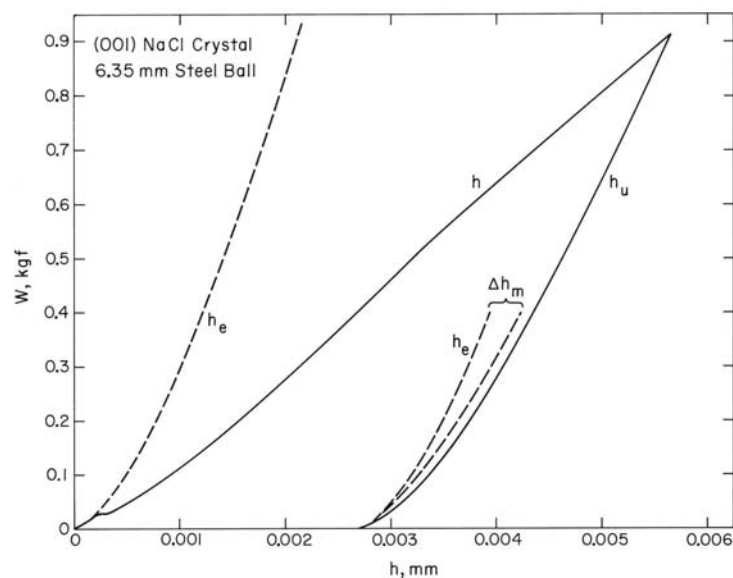

Fig. 6. Macroscopic loading curve for ball indentation in an (001) NaCl crystal surface [51].

closely the same Hertzian dependence. The effect was recently explained in terms of the negligible correction to the Hertzian behavior when only a small plastic strain, measured by  $(d/D)$ , is produced in the indentation test [52]. In the present case, the maximum value of  $(d/D) = \sim 0.06$ . And from the elastic prediction in Eq. (4) and plastic prediction in Eq. (9), the respective hardness stresses can be seen in Fig. 6 to be gauged by the ordinate slope to each point of the loading curve. Thus for NaCl, the elastic hardness initially rises to a highest value at the onset of plasticity and then drops to a lowest value at the terminal pop-in displacement to be followed thereafter by an increase with further plastic straining. Such continuous loading/unloading curves as shown in Fig. 6 were reported for terminal load values of 100 and 500 MPa. The unloading curves were steeper for the higher terminal loads. Similar measurements were made on KCl crystals. The alkali halide crystal work was followed by Robinson and Truman [53] who demonstrated application of the continuous indentation loading technique to produce a hardness-based stress-strain curve for aluminum material.

Figure 7 shows a compilation of hardness measurements, both obtained on a continuous loading basis for NaCl and for individual measurements for other crystal materials, all of which may be usefully compared on the framework of the proposed hardness stress – strain analysis [54]. The solid linear Hertzian dependence and follow on plastic stress – strain curve for NaCl is that determined from a result of the type shown in Fig. 6. The solid Hertzian line and other dashed ones shown in Fig. 7 were computed for a steel ball indenter. The terminal  $\sigma_c$  values shown for the dashed Hertzian curves were determined from Eq. (11) with employment of reported values of the cracking surface energy,  $\gamma$ . The value of  $\sigma_c$  for  $D = 0.124$  mm on the Hertzian curve for MgO, as compared to the lower value shown for a 6.35 mm ball, is raised in accordance with expressing Eq. (11) on a  $(d/D)$  strain basis. The smaller  $D$  value was determined for the diamond pyramid hardness ball size equivalent on a Tabor basis to the diagonal indentation size shown for the MgO crystal measurements, also plotted at an equivalent 0.375 value of  $(d/D)$ . The diamond pyramid hardness values are marked as VHN for Vickers hardness numbers in Fig. 7. As will be made clear for a number of experimental observations to be described in the present report, cracking at diamond pyramid hardness values frequently occurs at a lower hardness stress level than predicted for the Griffith-based indentation fracture mechanics stress of Eq. (11) because of the effect of stress concentrations at the tips of dislocation pile-ups, particularly, at slip band intersections. Such a result applies in Fig. 7 for the post-plastic yield stress measurements shown for the explosive crystal, RDX. In addition, Fig. 7 gives

Fig. 7. Hardness stress – strain results [54].

indication for MgO of a relatively larger elastic strain contribution to the total plastic ( $d/D$ ) value by virtue of the smaller separation of strain between the Hertzian elastic curve and the diamond pyramid hardness measurement, thus demonstrating the well-known observation that elastic recovery of the indentation shape is a relatively important consideration for harder crystals. Also, one might note the relatively greater brittleness of RDX compared to NaCl because of the smaller range between measured hardness and predicted cracking stresses. For RDX the indication is that there is little range in stress available for investigating any effect of deformation rate or temperature on the plastic deformation properties of the material.

### 2.3. Metrology considerations

The measurements provided thus far of the very significant range in load values applied to an indenter, say between  $0.2 \mu\text{N}$  in Fig. 1 and  $10 \text{ N}$  in Fig. 6 (with  $1.0 \text{ kgf} = 9.81 \text{ N}$ ), give indication that the main challenge of gaining an accurate evaluation of the hardness property comes not from measuring the load but from difficulty in determining the indentation contact dimensions during, or after, the hardness test.

#### 2.3.1. Indentation depth measurements

In a pioneering hardness study of nickel, gold and silicon materials, Pethica, Hutchings and Oliver reported indentation depths as small as  $20 \text{ nm}$  as revealed in the electron microscope, including continuous monitoring of the indenter penetration during loading and unloading [55]. There was concern for the importance of the un-assessed elastic strain during indentation. Nevertheless, the authors provided early quantitative measurements of an accompanying indentation size effect (ISE) that was associated with a higher plastic hardness being estimated for a smaller applied load coupled with smaller indentation size. The determination of higher hardness values at the smallest loads was attributed to very localized and enhanced strain hardening at the smaller indentations. An interesting observation was that small indents were able to be made in silicon without the material cracking.

An explanation of the ISE has been provided by Nix and Gao and leads to a predicted dependence of hardness on penetration depth of the form [56]

$$\sigma_{\text{Hp}} = \sigma_{\text{Hp0}}[1 + (h^*/h)]^{1/2}. \quad (14)$$

In Eq. (14),  $\sigma_{\text{Hp0}}$  is the extrapolated hardness at infinite depth and  $h^*$  is a characteristic length depending on the shape of the indenter, the shear modulus and  $\sigma_{\text{Hp0}}$ . Excellent agreement was demonstrated between Eq. (14) and experimental results reported from tests performed with a three-sided Berkovich indenter as applied to single crystals of copper and silver and to work-hardened copper material. For hardness measurements at such nano-scale level, the connection between  $h$  ( $= h_e + h_p$ ) and the contact area of an

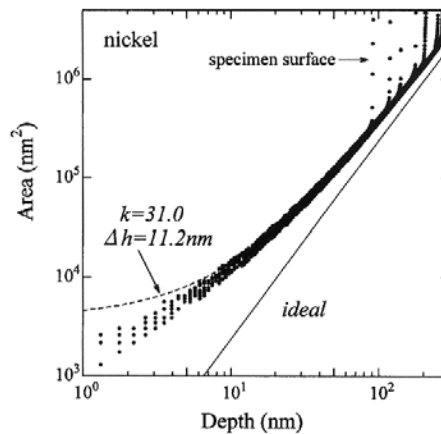

Fig. 8. Projected Berkovich surface area as a function of depth for  $0.41 \leq P \leq 4.2 \text{ mN}$  [57].

indentation is of important concern. In a related investigation, Miyahara, Nagashima and Matsuoda have produced Fig. 8 showing connection between indentation depth and corresponding surface area [57]. As noted in the figure, the measurements were achieved with combination of a silicon tip AFM probe and Berkovich (diamond) indenter but other materials were tested as well. The figure shows that the residual contact area was not reduced in direct relationship to the decrease in indentation depth and thus an ISE effect can be partly accounted for on such basis. The dashed curve shown in Fig. 8 was determined as a suitable area function to use in determining the material hardness. As will be described for other test results, particularly those involved in nanoindentation testing, the indenter tips are rounded in the same manner described by Hooke for his needle point when examined optically with a magnifying glass.

Another concern for the dimension scale at which interaction of an indenter tip and resultant specimen contact area occurs is shown in Fig. 9 for scanning probe microscopy results described by Coupeau, Girard and Rabier for a Berkovich indentation made under low-load condition in an MgO crystal surface [58].

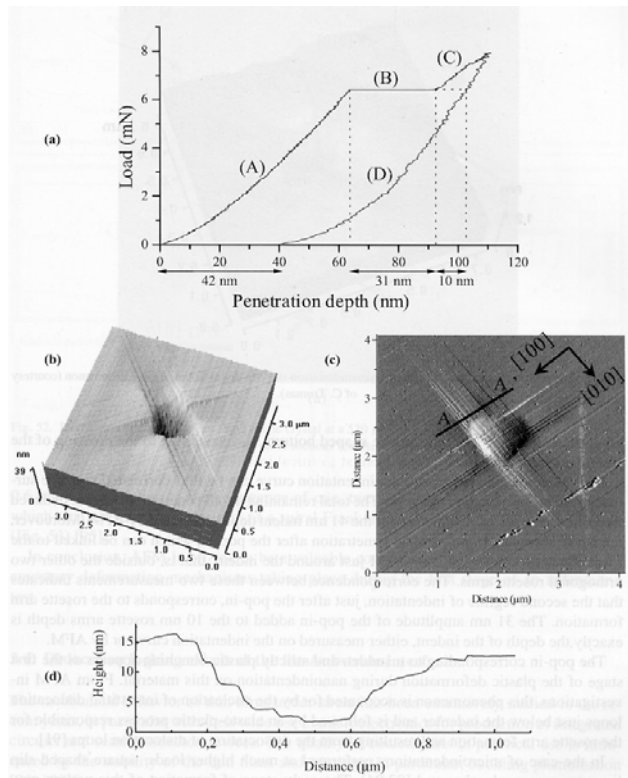

Fig. 9(a)-(d). Loading curve, surface appearance, and depth measurement for a Berkovich-tipped indentation in a (001) MgO crystal surface [58].

As shown in Fig. 9(d), Coupeau *et al.* produced a residual Berkovich indentation after loading to a total depth of ~110 nm with indenter alignment along the [010] direction of one edge of the three-sided indentation. The total indentation depth was sufficient to produce the remnant three-sided impression shown in Fig. 9(c). Equation (1) from Hertz was employed by Armstrong and Elban [59] to determine an indenter tip radius,  $(D/2) = 1.6 \mu\text{m}$ , for the initial elastic loading curve in 9(a). Figure 9(b) gives indication of indentation-forming screw dislocation “troughs” spreading along the paired (10-1)[-10-1] and (-10-1)[10-1] slip systems set in juxtaposition along  $\pm [010]$  directions and with (01-1)[0-1-1] and (0-1-1)[01-1] slip systems in the other orthogonal  $\pm [100]$  directions. The measured residual indentation depth along one of the two troughs of ~14 nm, as indicated in Fig. 9(d), can be compared with one-half of the residual indentation depth of ~42 nm, thus the two trough depths, and tracked screw dislocation displacements account for a major part of the indentation strain. Such measurements will be related in the current report to an aligned diamond pyramid indentation result also produced for an (001) MgO crystal surface but at sufficient load to produce cracking. In that case, as well as the present one, it is important to appreciate that

the elastic deformation, and its recovery, make an important contribution to the total deformation of indentations in MgO, consistent also with the hardness stress – strain measurements shown for MgO crystal hardness measurement in Fig. 7. Figure 10 shows quantitative assessments made by Shikimaka and Grabco of corresponding Berkovich and diamond pyramid (Vickers) indentations made in LiF and CaF<sub>2</sub> crystals including chemical etching of the dislocation “rosettes” and cracking observations [60]. The indentation-forming dislocation troughs pointed to in Fig. 9(c) are recognizable at the diamond pyramid indentation in Fig. 10(b).

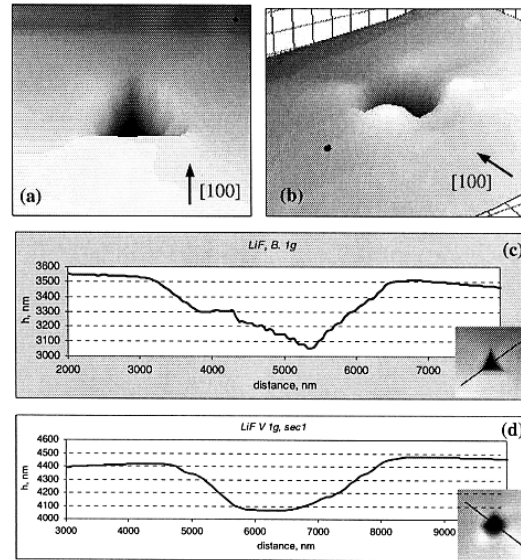

Fig. 10. LiF crystal 3-D images of Berkovich and diamond pyramid indentations at  $P = 10$  mN [60].

Other aspects of indenter penetration depth relationship to tip radius [61] and bluntness of the indenter tip [62] have been described. In the latter case, a spherical tip description was employed for relation to results obtained with a Berkovich indenter with a spherically-rounded tip applied to a fused silica glass and the load – penetration depth measurements were transformed to provide a stress – strain indentation curve. Berla, Allen, Han and Nix [63] have provided a two-parameter functional description of tip radius and equivalent cone slope for shape calibration of indenters. Observations have been reported of elastic-plastic contact area measurements made for copper and stainless steel spheres pressed against a flat transparent sapphire surface during loading - unloading tests [64]. Because of current concern for the direct imaging of indentations, Hou, Bushby and Jennett provided a comparison of optical microscopy, metrological force microscopy and confocal laser scanning microscopy methods for quantifying surface shapes of indentations and plasticity length-scale effects [65]. Another investigation has focused on measurement of the indentation strain pattern via digital image correlation for surface strains somewhat interfered with by out-of-plane displacements [66]. Even at micro-scale indentation level, there is concern for quantitative measurement of contact area because of pile-up or sinking-in around the indenter as described for *in-situ* measurements with a transparent spherical indenter applied to a relatively compliant polycarbonate material by Pelletier, Den Toonder, Govaert, Hakiri and Sakai [67]. Additional discussion will be given on this issue in other results that follow.

### 2.3.2. Advancements in hardness instrumentation/methods/techniques

There are improvements in instrumentation being made even at the smallest dimensional scale relating to atomic force considerations as described in the Introduction relating to Fig. 1. One improvement involves application of a “ferrule-top” optical system to cantilever design for a nanoindenter system [68]. Such design is proposed to extend AFM-based sensitivity to nanoindentation testing. A technique for AFM-based nanoindentation has been applied to measuring elastic and plastic aspects at nanometer dimensions of

grafted and spin-coated glassy polymethylmethacrylate (PMMA) thin films [69]. The mechanical dynamics of the cantilever systems employed in such measuring systems have been investigated [70]. Contact of a nanoscale tip and substrate has been modeled for a half-spherical platinum tip contacting a same material substrate for AFM action avoiding plastic deformation [71]. A force feedback system has been employed [72] to evaluate tip-surface interaction with sensitivity of 1 pN; see comparison with Fig. 1. From determined knowledge of the lever spring constant, simultaneous measurement was provided of force, force gradient and damping properties of the system.

A number of optical-based instrumented indentation systems have been developed for the direct determination of indentation hardness values, particularly, involving employment of a harder spherical indenter [73-75]. And a number of test conditions have been investigated, such as: effective indenter radius and frame compliance [76]; effect of friction [77, 78]; indenter misalignment relating to contact stiffnesses and Hertzian elastic prediction [79]; and, surface roughness [80-82]. Interesting additions relating to metrological aspects of the hardness measurement systems have been *in-situ* detections of acoustic emission [83] and Raman spectroscopy for phase transformation [84]. Cathodoluminescence measurements have been reported for gold sputter-coated nano-indentations in MgO crystals via an SEM fitted with a Cambridge S-180 cathodoluminescent measuring system [85]. Emphasis on indentation measurement aspects of hardness values have included length scale considerations [86], low temperature testing [87], quasi-nondestructive aspects of the test [88] and property measurements, including yield strength [89], accelerated creep behavior [90], viscoelasticity [91] and cavitation [92], in the latter case spanning the gap between relevance of nano- and macro-hardness considerations.

#### 2.4. Nanoindentation testing

In addition to the very important metrological advances directly associated with the advent of nanoindentation testing, there are a number of advantages relating to material properties that are able to be tested, for example: (1) an accurate method is provided to fully characterizing the elastic deformation behavior of crystals particularly during the initial loading behavior [52, 59]; and, (2) the opportunity is provided to probe the elastic/plastic transition behavior at pop-in type conditions at a smaller dimensional scale than the separation of pre-existent dislocations [93, 94].

Figure 11 shows an early comparison made on a hardness stress – strain basis of nano-scale indentation measurements [95] obtained with a (fixed-shape) trigonal diamond-pointed indenter applied on a continuous loading basis to a polycrystalline copper standard hardness test block: NIST Standard Reference Material No. 1894. The NaCl crystal stress-strain curve is that same result shown in Fig. 7 as obtained with a 6.35 mm steel ball. The several filled-diamond and inverted triangle points for silicon crystal

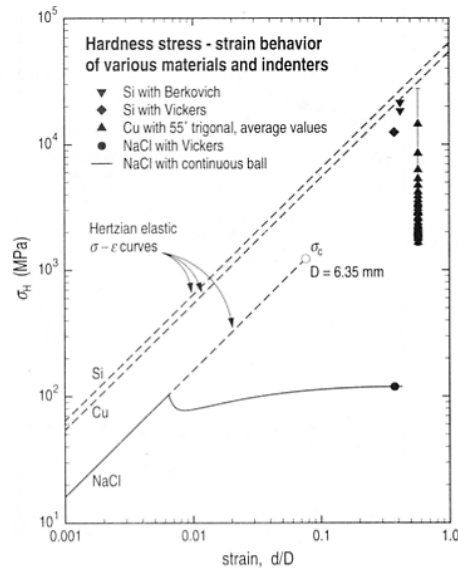

Fig. 11. Comparison of copper, silicon and NaCl results on a hardness stress – strain basis [95].

measurements are to be discussed in a later section of the current report. As noted the dashed Hertzian curve for copper lies just below that shown for silicon. The vertical stack of filled-triangle points plotted at a Tabor-type fixed value of  $(d/D)$  were determined on the basis of a fixed depth dependence of the contact area, as described for Fig. 8 above [57]. The lowest hardness value of 1.67 GPa was calculated at a highest load point of 200 mN to be in reasonable agreement with separate determination of a diamond pyramid hardness of 1.14 GPa at 500 mN load. The highest hardness values shown in the figure were determined with lesser certainty at lower load values in line with the same type of ISE that was described above for the pioneering results of Pethica *et al.* [55]. The highest hardness values were noted to approach the limiting Hertzian loading curve thus giving indication of comparable elastic and plastic strain values.

The results in Fig. 11 may be compared with somewhat similar nanohardness results reported by Lim and Chaudhri on polycrystalline annealed and work hardened oxygen-free copper materials [96]. In the latter case, a comparable range in load values of 1-100 mN was individually applied to a Berkovich indenter and accurate AFM measurements were made of the projected contact areas, including surface profile measurements for residual indentations obtained on both material conditions along one of the forward edge directions of the indentations. Significant elastic recovery could be recognized in the reported residual indentation shapes and was associated with either “piling-up” of material for the work-hardened case or “sinking-in” for the annealed case. From such actual area measurements then, a highest hardness value of only ~1.8 GPa was reported for an ISE effect for the work-hardened material (compared to lowest ~1.0 GPa value) and ~1.2 GPa (compared to lowest ~0.4 GPa) for the annealed case. Gerberich, Tymiak, Grunian, Horstemeyer and Baskes [97] have added to the interpretations of higher hardness for shallow indentation depths less than several hundreds of nms by pointing to connection of the ISE and ratio of energy for a newly-created surface and plastic energy dissipation.

Fig. 12. Hardness stress – strain curves for ZnO crystal C (basal) and A (prism) plane orientations [98].

Basu and Barsoum [98] have reported excellent results on application of the hardness stress-strain method to characterizing the plastic deformation behavior of ZnO C-basal and A-prism crystal surfaces in spherically-tipped nanoindentation tests as shown in Fig. 12. A lower hardness-based yield stress was associated with basal slip for the prism surface. The yield point drop is of the same pop-in type indicated in the macro-scale continuous loading result for NaCl in Figs. 6 and 7, only much more pronounced in nanoindentation tests [94]. The advantage of gaining information on the strain dependence of the hardness stress with a spherical indenter is made clear in Fig. 12. The additional inset figure shows an anelastic character for the post-yield indentation behavior of the C-plane indented crystal.

Kalidindi and Pathak have proposed a modified technique for transforming the continuous load-displacement curves into effective hardness stress – strain curves based on taking into account the indenter loading-unloading behavior [99]. There is indication, for example, of a stiffer unloading dependence in Fig. 12. Armstrong and Elban [52] have discussed the issue, particularly, relating to the result obtained from the Hertz equations that the effective elastic modulus,  $E_r$ , is easily obtained from the initial loading curve in nanoindentation tests after “seating” of the indenter on the specimen surface at a small value of  $(d/D)$ . Pathak, Shaffer and Kalidindi, in a follow-up report [100], have provided comparative indentation stress – strain curves for tungsten and aluminum materials indented with two ball sizes. The issue will be

revisited in the current report in the coming Section 3.1.1. Elastic loading results. For the present time, reference is made to work by Fischer-Cripps (see the book listings in Table 1) for providing example load-displacement curves [101], and to Bartier, Hernot and Mauvoisin [102] and Wei, Tsai and Lin [103] for further investigation of the contact radius associated with spherical indentations.

However, it is the obtainment of an improved understanding of the elastic – plastic “pop-in” transition that is of major interest in many nanoindentation experiments, as mentioned above [93, 94]. In the latter reference, Bahr, Jennerjohn and Morris employed the Hertzian – Hueber description of the elastic stress state below a spherically-tipped indenter to calculate, at the pop-in load level for a nickel crystal, a shear stress for dislocation nucleation approaching the perfect crystal theoretical limiting value. And subsequently in a number of articles [104-107], Bahr and colleagues have investigated the influence of solid solution impurities, atomic vacancies, point defects and stacking fault tetrahedra on dislocation nucleation at nanoindentations. Tai-Gutelmacher, Gemma, Volkert and Kirchheim have looked at the effect of hydrogen [108]. Such nucleation consideration should be influenced naturally by the contact area dependence on the indenter radius for any applied load value, for example, relating to the macro- to nano-indentation  $D$  values and pop-in appearances spanning the hardness stress – strain results shown in Figs. 7 and 12. Poon, Rittel and Ravichandran [109] have provided a mechanics analysis of such finite tip radius consideration by building onto the contact mechanics description originally developed for a sharp indenter tip with finite radius by Sneddon [110]; see the relationship to Boussinesq description given above for an infinitely sharp tip [23, 26] and Xu and Li [111] for connection of Sneddon and nanoindentation elastic-plastic behavior. The subject bears on the consideration of an essentially elastic unloading behavior after plastic yielding.

In two articles, one by Gao and Lou [112] and one by Lee, Bei, Morris, George and Gao [113], the nanoscale nucleation of dislocations under a wedge and matching of the small volume scales of contacted stress state and dislocation density have been modeled to provide a probability function for pop-in load characteristics. The pop-in stress is taken to be thermally-activated and so temperature and strain rate considerations are included. The model consideration of size scale is proposed to span the cases of homogeneous defect-free regions and heterogeneous mechanisms involving encompassed dislocation densities. Lodes, Hartmaier, Goken and Durst [114] have reported on connection of pop-in and ISE on dislocation density in  $\text{CaF}_2$  single crystals in furtherance of earlier work with colleagues [115] also connecting with macroscopic hardness and use of a model description employing geometrically necessary dislocations [116]. A contribution to the physics of the nano-induced plasticity has been given recently in an interesting article by Fujikane, Yokogawa, Nagao and Nowak [117]. Focus on the stress concentration to produce dislocation nucleation has been analyzed by Zhao, Ma and Korsunsky [118] in extension of previous work done with relation to cracking by Yan and Zhao [119]. A quantum mechanical description of solid solution effects on nucleation has been provided by Peng, Zhang, Huang, Carter and Lu [120].

Beyond the sensitive initial elastic loading behavior and pop-in type plastic yielding observations, the capability of nanoindentation testing is able to provide material strength measurements either not obtainable or not easily so by any other mechanical method. Thus, H. Huang, Wu, Wang, He, Zou, B.Y. Huang and Liu [121] have reported nanoindentation measurements made on tungsten microwhiskers significantly greater than for bulk material. Likewise, Daphalaparker, Wang, Fu, Lu and Komanduri [122], while Zou and Yang have reported hardness results in excess of 100 GPa for individual sand particles, and Zou and Yang [123] have reported measurements for silica nanoparticles deposited on a single crystal silicon substrate. And for mechanical probing within the finer cellular structure of a material, Konnerth, Gierlinger, Keckes and Gindl [124] have reported nanoindentation measurements obtained from wood. Reported measurements have ranged from such low hardness levels for wood and polypropylene [125] to nearly hardest results next to diamond of boron carbide [126] with in-between nano-hardnesses of beta-tin [127], indium and aluminum [128] and ZnO cone structures [129].

### **3. Elastic, plastic, cracking behaviors**

As indicated thus far in the present report, an important outcome of interpreting the continuous loading deformation behavior during indentation testing over nano-, micro-, and macro-scale behaviors was to provide a rather direct assessment of the elastic and plastic indentation deformation behaviors leading to a hardness-based stress-strain description. Beyond the early work described in references [50] - [54], Rickerby and Macmillan produced continuous loading curves for spherical indentation of a variety of materials including LiF, MgO and Ni crystals and with photographs of the resultant indentations [130].

Detailed optical, x-ray topographic and SEM photographs of [100] and [110] aligned micro-scale diamond pyramid indentations put into an (001) crystal surface had been reported by Armstrong and Wu [131], including discovery of the downward displacements at “troughs” produced by the indentation-forming dislocations in screw orientation (see Fig. 9(a)-(d) above) and with sufficient load application to produce cleavage cracking on vertical {011} planes. In follow-up work, Hammond and Armstrong [132] produced the results shown in Fig. 13 for an indentation with diamond pyramid edges aligned along the respectively-marked  $\langle 100 \rangle$  crystallographic directions. Details in the figure encompass considerations over the complete gamut of: (a) elastic recovery in the residual indentation depth and changed concave shape of the otherwise expectation of a square indentation pattern; (b) troughs produced by plastic flow of indentation-forming screw dislocations pushed away from the indenter tip as compared with volume-accommodating arrays of slip lines forming an apparent “picture frame” of indentation containment; and (c) surface cracking made visible along traces of the indentation  $\langle 110 \rangle$  directions by intersecting dislocation pile-up stress concentrations along internal  $\langle 111 \rangle$  directions of the juxtaposed {110} $\langle 110 \rangle$  slip systems not yet seen to be activated in Figs. 9(a) and (b). Feng and Nix [133] have investigated for MgO the ISE dependence predicted by Eq. (14). Significant deviation from the equation occurred for  $h$  values  $< 200$  nm, most likely related to the different stages of dislocation involvements indicated between  $h \approx 14$  nm in Fig. 9 and  $h \approx 3$   $\mu\text{m}$  in Fig. 13. Zong, Lou, Adewoye, Elmustafa, Hammad and Soboyejo have reported a bilinear ISE dependence for nano- as compared with micro-indentations made on (001) surfaces of nickel, gold and silver crystal surfaces [134].

Fig. 13. Aligned diamond pyramid indentation on (001) MgO crystal surface [132].

### 3.1. Elasticity

In the preceding description, the pioneering engineering mechanics analyses developed especially by Hertz [16, 17], Boussinesq [26], Hueber [18], Hencky [19], and Sneddon [110], have been referenced for contributing to a fundamental understanding of the elastic force-displacement relationship that develops during initial loading of an indenter pressed onto a contact surface.

#### 3.1.1. Elastic loading results

Early elastic loading in a continuous indentation test led to determination of the elastic deformation behavior of compliant lignin material extracted from wood and to estimation of its elastic modulus,  $E_S$  [135]. Yoffe employed the loading curve in a re-examination of the Hertzian relation leading to a correction at larger displacements [136]. Useful elastic relations for other indenter shapes are also given by Yoffe. The preceding results relate to the elastic or viscoelastic indentation behaviors of other “softer” materials. For relatively compliant rubber-like materials, Liu, Zhang and Sun have described application of the Hertz equations to the load-displacement relation obtained for spherical indentation results at relatively small ( $d/D$ ) values and make connection with Sneddon’s solution [137]. A finite element description is developed for application up to  $(h/D) \approx 0.4$ . Chen, Wang, Huan and Luo present a three-dimensional

model for viscoelastic contact on polymer-based materials with modification of Hertz's  $E_r$  to be time-dependent [138]. And, Dokukin and Sokolov describe obtaining of bulk modulus ( $E_r$ ) for polyurethane and polystyrene polymers with micrometer AFM tip probes with  $D = 1.62 \mu\text{m}$ , and  $2.04 \mu\text{m}$ ; measurements made with a  $D = 44 \text{ nm}$  tip involved interference both from a "skin effect" and probe-surface adhesion [139]. Kindrachuk, Galanov, Kartuzov and Dub report the obtaining of  $E_r$  values for LiF and KCl crystal surfaces with a blunted Berkovich indenter [140]. Other reports on the topic have included investigations of a piecewise description of elastic influence of indenter shape [141] and an effect of surface roughness [142]. Several reports have dealt with the general determination of Young's modulus and separation of Poisson's ratio in  $E_r$  [143-145].

A direct nanoindentation measurement of the initial elastic loading/unloading behavior of an  $\alpha\text{-Al}_2\text{O}_3$  basal (0001) single crystal surface is shown in Fig. 14, as obtained by Lu, Mai, Tam and Shen, also with indication given within the figure body of excellent fit to the Hertzian Eq. (1) elastic dependence [146]. The sapphire crystal result was obtained with a Berkovich indenter and rounded tip of estimated  $D \approx 408 \text{ nm}$ . Pop-in displacements were obtained beginning at the larger load value of  $1300 \mu\text{N}$ . Plastic hardness values were determined through employment of an area function (see Fig. 8 and reference [57]) and shown to be in agreement with the predicted form of Eq. (14) from Nix and Gao [56]. A theoretical Hertzian shear stress of  $28.2 \text{ GPa}$  was estimated for the pop-in initiation of plasticity. In relation to the plasticity

Fig. 14. Elastic loading/unloading of an  $\alpha\text{-Al}_2\text{O}_3$  (0001) crystal surface [146].

observations made by Lu *et al.*, Lloyd, Molina-Aldareguia and Clegg [147] had previously identified, with the TEM applied to cross-sectional slices through nanoindented (0001) crystal surfaces of sapphire, operation of the three slip planes: basal, pyramidal (-12-13) and prism (-1210). Results were also reported for spinel and magnesia crystals. In follow-up tandem articles on aspects of nanoindentation-induced plasticity in sapphire, Tymiak and Gerberich presented: first, scanning probe microscopy images of the surface indent topography revealed at spherical indents on basal, rhombohedral (-1012), and both prism (10-10) and (1-210) surfaces, and model analyses of them; and then secondly, load-displacement curves for various yield point-type pop-in behaviors [148]. The pop-in displacements were correlated with acoustic emission signals. And, most recently, Mao and Shen have reported on the pop-in characteristics of Berkovich-type nanoindentations put into sapphire rhombohedral (10-12) crystal surfaces, including estimation of the (10-11)[12-10] slip system being dominant and analysis of ISE measurements on Nix-Gao [56] and another basis [149]. Figure 15, from Gaillard, Tromas and Woizard, demonstrates for an nanoindentation of an (001) MgO crystal surface the sequential initial elastic loading behavior interrupted at several stages by plastic pop-in displacements [150]. The incipient plastic displacements produced by dislocation pile-ups contained within individual slip lines were monitored by application of chemomechanical polishing (CMP) for surface layer removal and of dislocation etching of the resultant indent. The nanoindentation result shown in Fig. 15 was obtained with application of a spherical diamond tip with  $D = 20 \mu\text{m}$ . In several experiments, the nanoindentation test was halted after individual pop-ins to demonstrate that each one was associated with nucleation of a new slip line structure. Quantitative measurements were reported for the number of dislocations in a slip line and the pile-up positions along the

slip line commensurate with determinations from the loading curve of the Hertzian elastic contact radius just before first pop-in. Results from surface layers removals of up to 350 nm were reported.

Fig. 15. Elastic-plastic nanoindentation loading curve for an (001) MgO crystal surface [150].

Gaillard et al. indicate in Fig. 15 that elastic loading resumed after the first two pop-in displacements. Also, it may be noted that a total displacement of  $\sim 180$  nm was achieved in this particular test thus corresponding to a total value of  $(d/D) \approx 0.19$  (and consequent relatively low terminal hardness stress  $\sigma_p \approx 4.5$  GPa; see Fig. 7 for comparison). Furthermore, it might be noted that the unloading curve from the terminal load value is not very much different in its displacement dependence from the Hertzian curve shown to be extended from the start of loading. The elastic loading and unloading comparison relates to an important method developed by Oliver and Pharr [151] of providing for determination of  $E_r$  from the top unloading part of a plastic loading curve after reaching the terminal loading value. The method was shown to give good results for fused silica, soda-lime glass, and single crystal sapphire as well as aluminum, tungsten and quartz crystals. The procedure involves determination of a modified indentation depth to be used in conjunction with the indenter shape function to establish the contact area at terminal load. Miyahara et al. [57] have commented on such connection in relation to the contact area function shown here in Fig. 8. The issue also relates to Armstrong and Elban having pointed to the Hertzian prediction of the elastic load-displacement relation also depending on a radius of contact for the pre-indented contact surface; and, a reliable value of  $E_r$  being obtained from the initial loading curve if only a small pre-strain is applied to insure proper contact of the indenter [52]. Ferranti, Armstrong and Thadhani [152] have reported on a comparison of the two  $E_r$  determination methods at macro-scale dimensions for determining the lignan  $E_r$  described above [135] while also employing the Hertzian description for determining  $E_r$  values for fully dense and porous aluminum materials. Feng, Tannenbaum, Kang and Alvin have reported on a multiple partial unloading method for determining  $E_r$  in microindentation testing of steel, aluminum, bronze and single crystal superalloy materials [153]. Gao and Pharr have extended the Hertzian analysis to predict an elliptical contact area for an elastically anisotropic crystal and provided an example calculation for spherical indenter contact on a moderately anisotropic aluminum (110) crystal surface [154]. Other reports have been concerned, in one case, with employing the method of Oliver and Pharr [151] to investigate the relationship between an indentation-determined elastic modulus and the corresponding material hardness [155], or, in a second case, to investigate the connection between elastic and hardness anisotropies measured by Knoop hardness testing of iron pyrite single crystals [156]. As an example of practical application, Chromik, Vinci, Allen and Notis have reported determination of nanoindentation  $E_r$  and hardness measurements for lead-free solder and tin-based intermetallic materials, also with complementary AFM measurements of the residual indentation profiles [157].

### 3.1.2. Elastic/plastic rebound

The separation of ball bearings into different bins according to how they bounced was tracked by Walley [1] to a 1917 report on quality control of manufactured steel bearings. The test relates to subsequent results of Tabor [37, 38] and to a mid-20<sup>th</sup> century application by Vincent, Gee and Hunter

[158] of comparing Hertzian prediction [159] for the elastic rebound mechanics of steel ball impacts and a time-dependent model description for the initiation of rate-dependent plasticity. For elastic rebound of a ball of reduced mass,  $(m_B m_T / [m_B + m_T]) \approx m_B$  impacting a flat (target) surface of substantially greater mass,  $m_T$ , the Hertzian contact time,  $t$ , is given by

$$t = 2.94(15m_B g/16)^{-2/5} (D/2)^{-1/5} v^{-1/5}. \quad (15)$$

In Eq. (15),  $m_B$  is the mass of the ball,  $g$  is acceleration due to gravity, and  $v$  is the velocity on impact. Vincent et al. employed a comparison of contact  $t$  in Eq. (14) for first impact and a reduced contact time after multiple impacts, along with a dislocation mechanics-based plasticity analysis, to determine the dynamic yield stress of mild steel material. Initial and multiple impact tests were conducted in a controlled velocity apparatus with ball diameters of 40.8 and 70.6 mm diameter impacting at individual ball velocities within the range of 20 - 40 cm/s. The Hertzian prediction for initial contact durations was confirmed by comparison of results for the two ball sizes. The model plasticity description employed the Hertzian maximum value of shear stress at  $(D/2)$  below the indenter and, with assumption of a spherical plastic impression being obtained after multiple impacts, led to prediction of a reduced time dependence on number of impacts.

Tirupataiah, Venkataraman and Sundararajan described gravity-dropped ball impact results for Hertzian prediction of the coefficient of restitution, as rebound velocity divided by impact velocity, for a variety of metals and including assessment of cratering produced by plastic deformation [160]. A comparison was made of dynamic and static hardness values. Argatov and Fadin have reviewed the Hertzian elastic problem for spherical impact in connection with an extension to consideration of plate impacts [161].

Fig. 16. FEM modeled elastic sphere impact on an elastic-perfectly plastic substrate [162].

Wu, Thornton and Li have investigated the effect of plastic deformation of a substrate on the rebound behavior of an elastic sphere by means of the finite element method employing the DYNA3D15 code [162]. Figure 16 illustrates the comparison with Hertzian prediction of the vertical contact force-displacement relationship at different impact angles,  $\theta$  from a vertical direction for a perfectly plastic substrate. A sphere of radius  $(D/2) = 10 \mu\text{m}$  was assumed and a constant normal velocity of 5 mm/s. Very interestingly, the comparison of the terminal Hertzian loading result and final unloading displacement shows that a major portion of the permanent deformation occurs during the rebounding action. Normal coefficients of restitution values were also obtained as a function of the ball contact time.

Clough, Webb, and Armstrong have reported comparison of high deformation rate dynamic hardness values obtained in dropped ball experiments and strength measurements obtained in conventional high rate tensile deformations [163]. The measurements were interpreted in terms of a dislocation mechanics-based constitutive relation employed for material dynamics calculations, not unlike the pioneering description employed by Vincent et al. [158] in their controlled velocity impact tests. Tirupataiah and Sundararajan have reported on further investigation of the cratering aspects of dynamic impacts [164]. The topic has been reviewed by Sundararajan [165].

For a condition of much greater deformation, the so-called “deep penetration” of a rigid sphere under hypervelocity impact conditions has been analyzed much earlier by Hanagud and Ross [166] in terms of a

continuum plasticity description of a dynamically expanding cavity. The topic relates to modern constitutive equation applications to actual material deformations under extreme loading conditions as recently described by Murr [167], including the use of hardness testing as a probe for correlation with changes in microstructure. For the case of more brittle material behavior, Chaudhri [168] has presented a review of his own researches on sequential high-speed imaging of indentation-type cracking initiated within a KCl crystal by impact of a tungsten carbide sphere at a velocity of 145 m/s. The associated plastic deformation was interpreted in terms of dislocation velocities reaching up to 700 m/s. Leavy, Brannon and Strack [169] have reported on spherical indentation experiments employed to characterize damage in ceramics and particular results have been reported for silicon carbide material by Holmquist and Wereszczak [170].

### 3.2. Plasticity

Beginning from the original work of Brinell [28, 29] and others to use hardness determinations to assess the smallest amount of plasticity associated with brittle cracking of ceramic materials, and as indicated for many of the reports thus far referenced, there was a second thread of employing indentation hardness testing to investigate the crystallography of deformation systems beginning with optical microscope observations made on minerals and eventually extending to dislocation interpretations of plasticity.

#### 3.2.1. Slip, twinning, dislocation observations

Interest in the abrasive hardness of minerals, for example, as associated with Mohs [171] in the 19<sup>th</sup> century, was rekindled in the 20<sup>th</sup> century by Schmid and Boas [172] in their book on crystal plasticity. Among the grand tabulations of crystal deformation and cleavage systems in the latter book were important references to Reis and Zimmermann [173] and Prizbram [174] on the Brinell hardness of alkali halide crystals. Gilman took up the topic by correlating the hardness of alkali crystals and their ionic bonding [175] after having first tackled the bonding – structure relationships for metal-metalloid type carbides and refractory hard metals [176] crystals. Later attention was given to covalent bonding and the hardness of semiconductors [177]; see the listing for Gilman's book in Table 2. The difficulty of dislocation movement was especially considered in terms of atomic forces determining the crystal structure. Currently, specification of the hardness properties of crystals in relation to their operative dislocation-based slip and twinning systems and the consequent dislocation interactions is a main activity covering the complete range from softest to hardest material structures.

A number of reports have dealt with the hardness of diamond and superhard crystals [178-180], including claims of dislocation movement at ambient temperature. There is always the question of having a nindenter that is sufficiently hard or, alternatively, of investigating the indirect effect of deformation occurring both by the indenter and material being investigated, as mentioned above with respect to

Fig. 17. Slip steps at an MgO (001) crystal surface indentation site produced at ambient temperature by a flattened copper cone subjected to a mean pressure of 700 MPa [181].

references [14] and [15]. In an investigation of the latter type concerning the hardness of diamond under high temperature – high pressure conditions, Brookes, Howe and Parry obtained the image shown in Fig. 17 of slip bands in an (001) MgO crystal surface produced by a flattened copper cone [181]. The circular imprint of the flattened cone is marked by the segmented length of the slip bands. Note that the reported mean pressure given in the figure caption corresponds under the specified conditions to a hardness value of one-tenth of the average hardness value shown for ambient temperature measurements in the hardness stress – strain curve of Fig. 7.

Stokes, Johnston and Li [182] reported early bend test results for MgO in which slip band development was initiated from dislocation sources put into the crystal surfaces. Other work by Stokes and colleagues had established by means of birefringence observations the importance of dislocation pile-ups forming at slip band intersections and initiating cleavage cracks. Pande and Murty described {100} type slip band structures produced under dynamic indentation loading in NaCl crystals [183]. Gallagher, Halfpenny, Miller and Sherwood [184] reported on the observation of slip systems in PETN and RDX energetic crystals; see the representative hardness values from other measurements that are plotted in Fig. 7. A stereographic method of analysis applied to slip line patterns observed at diamond pyramid indentations in oxidizer ammonium perchlorate crystals was reported by Elban and Armstrong [185]. Nibur, Akasheh and Bahr reported on the use of surface observations of slip step structures around indentations in a procedure to analyze internal dislocation reactions [186].

### 3.2.1.1. Dislocation rosettes

Chemical etch pits produced at points of emergence of dislocation lines on the surface of individual crystals have been an extremely valuable source of tracking dislocation mechanisms involved both in crystal growth and plastic deformation. Gilman reported on the chemical details of etch pit formation at dislocations in LiF [187]. In later deformation studies, Johnston and Gilman [188] investigated the stress dependent velocity of dislocations by employing ball impacts from a pendulum test system; see also a review of the pioneering work [189].

In the report by Stokes et al. [182], dislocations had been introduced into the crystal surface by microscopic impacts from sprinkled carborundum particles in the referenced MgO work by Stokes. The reported “rosette” structures may be seen to be precursors of the now-familiar dislocation rosettes produced in many microhardness studies such as first reported for MgO by Keh [190] and for other alkali crystal results reported by Urusovskaya and Tyagaradzhian [191] and by Pariiskii [192]. In subsequent researches, indentation-produced rosettes have been investigated in metal, covalent and molecular crystals, for example: by Chen and Hendrickson [193] in silver at diamond pyramid indents under 0.2 mN load; by Hu [194] in silicon crystals at temperatures  $\geq 673$  K and at loads  $\geq 20$  mN; and in PETN and RDX molecular (energetic) crystals by Halfpenny, Roberts and Sherwood [195] and also by Elban and Armstrong [196, 197] in RDX at Knoop and diamond pyramid indents under loads  $\geq 0.5$  N sufficient to produce cracking; see the reference diamond pyramid hardness values plotted in Fig. 7. Punched-out dislocation rosettes at indentations in copper have been reported by Miura [198]. The effect of oxygen on dislocation locking in

Fig.18. Schematic dislocation structure at aligned MgO indentation [131].

silicon was investigated by Harada and Sumino for rosettes produced in silicon at different temperatures [199], thus relating to Westbrook's concern with the temperature dependence of hardness [46]. Nanoindentation rosettes have been reported for barium titanate crystals [200] and ZnO [201]; see in the latter case connection with reference [98].

Study of dislocation rosettes in MgO and LiF crystals has been a particularly active topic of research extending over dimensional scales from those associated with optical microscopy and x-ray diffraction topography to SEM [131, 202], TEM [203], and AFM imaging [204]. Figure 18 shows a schematic diagram of the dislocation structure and induced cracking associated with the type of aligned diamond pyramid indentation shown for the MgO crystal surface in Fig. 13 [131]. In Fig. 18 [131], the orientation of the aligned indentation and of the crystal-lattice-determined dislocation slip structures combine to produce the concave edges of the residual indentation, especially relating to the troughs along  $\langle 110 \rangle$  directions produced by the indentation-forming dislocations emerging in a screw orientation on the (001) crystal surface [200]. The same orientation consideration was shown to change the shape of the indentation edges to a convex shape for an indentation rotated by 45 degrees so as to produce side edges along  $\langle 110 \rangle$  directions, as can be observed by close examination of Fig. 19 that is an optical transmission micrograph obtained with a beam polarizer for a LiF crystal [205]. The somewhat rounded edges of the indentation connect the central white cross formed in the figure by the indentation diagonals.

Fig. 19. Transmission optical photo with  $\langle 011 \rangle$  axis polarizer of an aligned diamond pyramid indentation with edges along  $\langle 011 \rangle$  directions in LiF (100) crystal surface [205]; see reference [131] for comparison with MgO  $\langle 001 \rangle$  edges.

A hardness of 1.41 GPa was obtained for the LiF crystal shown in Fig. 19. The birefringent pattern shows contrast produced by greater light intensity being transmitted alongside the diagonal  $\langle 110 \rangle$  directions perpendicular to the indentation side edges. Figure 18 shows that arrays of edge dislocations arranged in a dipole-like structure emerge along these directions. No influence on the transmitted light appears to be associated with the screw dislocation arrays aligned in the  $\pm[001]$  and  $\pm[010]$  directions. The substantial dilatation-associated edge dislocation contrast and consequent absent contrast for the screw dislocation arrays is in agreement with the previous work of Mendelson [206] on observation of birefringence in glide bands in NaCl single crystals being attributed to edge (and not screw) dislocations.

Gaillard, Tromas and Woïrgard related the observation of dislocation rosette structures and the occurrence of pop-in behavior in the load-displacement curves of nanoindentations made on MgO and LiF crystals [204, 207]. Slip step heights of 0.21 nm were measured [204]. Fig. 20 shows A and B cases of rosettes obtained in an AFM tapping mode operation and corresponding pop-ins at load values of  $\sim 0.13$  and  $\sim 0.4$  mN measured with a Berkovich indenter, respectively [207]; see reference [58] and Fig. 9(a)-(d). The elastic loading behavior was associated with the description for an axisymmetric indenter given by Sneddon [208]. The absence of evidence of dislocation slip activity along the  $\pm\langle 100 \rangle$  directions is puzzling. Sufficient deformation was imposed to make visible the triangular impression of the Berkovich indenter but not in sufficient depth to activate the volume-accommodating dislocation slip bands that form the "picture frame" encasement shown schematically in Figure 18. Other deformation curves were shown of unloading results obtained after different amounts of post-pop-in deformations. Discussion centered on the rosette pattern at B that was initiated at lower load but was pushed to further extent by the continued

Fig. 20. Dislocation rosettes in LiF with associated nanoindentation pop-in curves [207].

loading that is shown and was compared with the reverse situation of seemingly greater pop-in nucleation at higher load for A but without adding to the extension of the rosette pattern by further loading. Emphasis was given to a high and localized dislocation density being nucleated during pop-in and being formed within a small volume. Such observation relates to the description by Gane and Cox [13] for the ISE being associated with a highly localized volume of straining. Dong, Huang and Kang have investigated the nature of pop-in events occurring for nanoindentations made on both (001) and (110) crystal surfaces of MgO crystals and correlated the observations with Hertzian prediction of shear stresses and with acoustic emission measurements [209]. A greater shear stress was estimated for slip on the {100} planes as compared with the {110} planes. Savenko and Shchukin present an interesting comparative analysis of the separate lengths of etch pit extensions in  $\langle 100 \rangle$  and  $\langle 110 \rangle$  directions in NaCl and LiF crystals [210].

### 3.2.1.2. X-ray diffraction (topography)

The observation via x-ray diffraction contrast of lattice strains produced by the residual dislocation structures at plastic indentations potentially provides an additional technique for deciphering the role of dislocations in effecting the hardness of crystals [211]. In particular, the back-reflection method, whether done by the conventional Berg-Barrett employing characteristic radiation or by the crystal-monochromated, asymmetric crystal topography (ACT) method [212], affords insight into the generally more complicated nature of internal dislocation interactions determining the yield and strain hardening properties involved in determining crystal hardness values; see reference 131 for diffraction contrast produced at hardness indentations in an MgO crystal under different applied loads. Raghuram and Armstrong [213] matched the

extent of etch pit rosettes and x-ray diffraction contrast at indentations on MgO. Yoo, Rosemeier, Elban and Armstrong extended the x-ray measurements to comparison of optical and x-ray diffraction patterns for indentations at macroscale sizes [214]. Use of a synchrotron x-ray diffraction provides a very useful method of obtaining more accurate measurements more quickly [215].

An interesting application of x-ray diffraction topography has been to investigate the hardness properties of energetic (explosive) crystals which are relatively brittle and otherwise decompose in the electron microscope [216]. The crystals are elastically compliant but relatively hard [197] as previously pointed-to in Fig. 7. Both diamond pyramid and Knoop hardness measurements were reported for crystal faces of RDX whose identifications were confirmed by x-ray diffraction [217]. Comparative etch pit rosettes and (Berg-Barrett) x-ray reflection topographs obtained for LiF and RDX led to explanation of the RDX crystal hardness being attributed to difficulty of dislocation movement through the intertwined molecular structure of the orthorhombic crystal lattice [197, 218]. Halfpenny, Roberts and Sherwood have reported in a series of articles very complete crystal growth, (Lang) x-ray transmission topography, and hardness results obtained on PETN crystals [195, 219, 220] and also to RDX crystals [221, 222].

Figure 21 shows application of the ACT reflection method to reveal the internal diffraction contrast at a central diamond pyramid indentation placed at 100 g load with vertical diagonal length along the [100] direction into a (1-10) copper crystal surface and with accompanying smaller indentations put at 5 g load into the strain field of the larger indentation [223]. The complex geometry of white lobes centered on the indentation account for an absence of diffracted intensity. A stereographic method of analysis was employed to describe the physical diffraction geometry and to demonstrate a procedure for determining the crystal lattice rotations involved in producing such strain patterns. The more easily deciphered strain contrast was illustrated for the strain pattern of a Knoop indentation.

Fig. 21. X-ray diffraction (3-1-1) topograph of a central large diamond pyramid indentation with diagonal axis aligned along [110] on (1-10) copper crystal surface, and with smaller indentations in the [100] above and along the [110] horizontal centerline [223].

The x-ray diffraction contrast obtained from the internal strain pattern in Fig. 21 may be compared to some extent with the AFM surface profile measurement shown in Fig. 22 for a nanoindentation put into a same-oriented copper crystal; note the similar appearance of the two lobes along the  $\pm[1-11]$  directions [224]. Wang, Raabe, Kluber and Rotors obtained Fig. 22 for a conical indentation so as to place emphasis

Fig. 22. AFM contour image of pile-up pattern at conical indent on (011) copper crystal surface [224].

on the surface pattern measurement being solely determined by response from the crystal lattice. Simulated surface contour plots were also obtained to show reasonable agreement via mechanics modeling on a crystal slip plasticity basis and employing the FEM code MARC and HYPEL2 subroutine2. Good agreement was obtained for other AFM and modeled patterns of indented (001) and (111) crystal surfaces. Locally changed crystal texture measurements in the indents and in their surrounding regions were mapped by means of a high resolution electron back-scatter diffraction (EBSD) technique so as to follow the more-complicated slip system rotations, not unlike that involved experimentally in Fig. 21. The use of EBSD determinations for obtaining “orientation micrographs” at plastic indentation zones covering dimensions from 250 nm to 250  $\mu\text{m}$  has been described by Rester, Motz and Pippin [225]. Two-fold, three-fold and four-fold symmetry for respective nanoindentations on (011), (111) and (100) copper crystal surfaces were determined and experimentally simulated by Liu, Varghese, Ma, Yoshino, Lu and Komanduri [226].

Other x-ray application has involved the very appreciable “time-saving” application of synchrotron radiation to obtain microdiffraction measurements of lattice rotations at indentations in single crystal copper [227], relating to the ISE, and for assessing nanoindentation determinations of residual stresses around micro-scale scratches scribed into aluminum alloy materials [228].

### 3.2.1.3. Electron microscopy

A number of hardness results obtained with electron microscopy techniques have already been described. Beyond observation with the SEM of intimate tungsten indenter contact with the gold substrate shown in Fig. 2, and such observation leading to quantitative sub-micrometer scale measurements of the indentation size effect [13], SEM application provided first detection of the downward surface troughs shown in Fig. 13, thus leading to description of the indentation-forming screw dislocation patterns surrounding indentations in the (001) surfaces of MgO crystals [131]. The technique has been put to use for examination of dislocation rosettes at finer resolution than can be done with conventional optical microscopy. Valuable observations and quantitative measurements have been obtained at finer dimensional scale with the scanning tunneling microscope as referenced in [8] for nm-scale slip step heights at a nanoindentation in gold and for atomic force microscopy results illustrated in Fig. 9(a)-(d) for a nanoindentation in an MgO (001) crystal surface [58], including in the latter case, the mentioned troughs at the earliest stage of plastic deformation.

Chaudhri, Hagan and Wells obtained information on atomic color center activity at indentations in MgO crystals through the use of cathodoluminescence (and photoluminescence) measurements made at relatively low applied voltages in conjunction with SEM observations [229]. While strong luminescence was observed outside of the physical size of the residual indentation, a complete absence of effect was observed within the actual projected area of the indentation itself. The luminescence was attributed to the strain-induced creation of color centers at atomic defects. The effect was substantially quenched within the immediate confines of the indentations [230, 231].

The TEM was employed by Gane [14] to obtain the pioneering shadow micrographs shown in Fig. 3, otherwise the technique has been employed for the principal purpose of observing dislocation structures produced at nano- and microindentations and quantifying the individual dislocation characteristics and arrangements, as reviewed by Chaudhri [168]. The observation by Humble and Hannik [179] of dislocations in ambient temperature indented diamond is an excellent example of expert TEM application. In general, the TEM has provided such observations in association with ultra-fine scale indentation loadings and the consequent deformations. An exception is provided by Chaudhri who points to the use of the TEM to investigate the relatively higher density dislocation structure immediately below an indentation. In silicon, TEM and selected area electron diffraction patterns were employed to investigate, in addition to dislocation initiations, whether the material had become amorphous and/or whether allotropic phase transformation had occurred. Minor, Lilleodden, Jin, Stach, Chrzan and Morris have presented evidence of room temperature dislocation plasticity in silicon using *in-situ* nanoindentation in the TEM [232]. The observation of dislocation plasticity was attributed to a special effect of free surface dislocation nucleation being favored in their test system. Alternatively, Das, Dhara, Jeng, Tsai, Hsu, Raj, Bhaduri, Albert, Tyagi, L. Chen and K. Chen [233] report direct observation of amorphization of p-type silicon under an indentation by means of accompanying *in-situ* Raman spectroscopy measurements at  $\sim 1$  micrometer spatial resolution of the probing laser beam. Load-indentation depth curves were obtained under different low rate loading conditions, including pop-in observations and “pop-out” steps in the unloading curves. More recently, Chrobak, Tymiak, Beaver, Ugurlu, Gerberich and Nowak have explained the observation of

dislocation plasticity on Hertzian-interpreted compression of Si nanospheres on the basis of a lesser constraint being provided by the smaller crystal sizes [234]. Hardness stress – strain curves were reported along with MD model calculations for confined (bulk-type) and unconfined (nanosphere) conditions. A two-times higher strength of ~22.4 GPa was reported for the compressed nanoparticles controlled only by plasticity as compared with the lower strength plasticity of bulk silicon associated with its phase transition.

Other researches by Nowak, Chrobak, Nagao, Vodnick, Berg, Tukianen and Pessa [235] have focused on an electrical spike measurement made during pop-in at the end of the elastic loading part of *in-situ* nanoindentation experiments performed on GaAs crystals. The “mystery” of the measurements has been explained recently in terms of a simultaneous phase transformation from the zinc blende to rocksalt lattice structure [236]. Interatomic distance and bond angle measurements made during the experiment have been correlated with *ab initio* density functional model calculations of the indentation process.

#### 3.2.1.4. Atomic force microscopy/Atomic modeling

Beyond the inventive relationship between the techniques of AFM for observing atomic-scale structure and development of instrumentation for nanoindentation hardness testing [6-10], there are the direct applications of employing AFM observations in order to better understand material indentation properties; see Figs. 9, 10, 20 and 22. Earlier AFM observations had been made on MgO crystals relating to nanoindentation creep [237] and detection of plasticity on direct loading [238]. Gaillard, Thomas and Woïrgard correlated plasticity observations with sub-surface dislocation positions that were revealed by chemical etching after removal of the nanoindented crystal surface layers in-depth by chemo-mechanical polishing [239]. An AFM investigation has been reported by Tall, Coupeau and Rabier of deformation twinning initiated at diamond pyramid indentations made at various temperatures in LaAlO<sub>3</sub> crystals, and especially for twinning occurring at the tips of cracks when subjected to sufficient applied load values [240]. Chromik, Vinci, Allen and Notis have described AFM results obtained on nanoindentations placed within individual grains of Pb-free solder and Sn-based intermetallic materials [241].

The experimental AFM observations lend themselves to comparison with atomic scale modeling, particularly at the dimensional scale of nanoindentations [242]. Thus, Szlufarska has reviewed MD simulation of nanoindentation load - depth curves obtained on SiC material, nickel indentation of gold, diamond pyramid indentation of Si<sub>3</sub>N<sub>4</sub> material, and MD and FE simulation of nanoindentations in copper. A number of atomic scale images are contained in the article, including nanoindentation probing of grain interiors and grain boundary effects in gold and in SiC. In coupling atomistics and discrete dislocation (CADD) plasticity modeling, Miller, Shilkrot and Curtin have given emphasis to the same attractive size scale consideration of nanoindentation dimensions and simulated modeling of results [243]. At increasing depth below an indentation, their model development includes dislocation nucleation, dissociations, interactions, hardness size dependence, surface uplift, reverse plasticity, among other details. For the purpose of investigating deformation-induced “hot spot” development in energetic crystals, Chen, Nomura, Kalia, Nakano and Vashishta have provided MD simulations of temperatures generated in an RDX crystal when indented at nanoscale dimensions [244]. A comparable hardness of 391 MPa was obtained, somewhat greater than the average measurement shown for RDX in Fig. 7. Other simulations have been reported for alumina (ceramic) [245] and for polymer [246] materials, in the former case, involving very significant plastic anisotropy for indentations on different crystal faces, and in the latter case, relating indentation test results obtained on epoxy materials to their glass transition temperatures.

Both AFM nanoindentation experiments and modeling of results are particularly interesting for metals because of their exhibiting relatively high elastic stiffnesses and greater difficulty of nucleating dislocations that otherwise spread easily, thus leading to rapid elastic loading to a pop-in stress with substantial displacement. Figure 23 shows two load-displacement curves obtained at constant loading rate for a nickel (111) crystal surface [94]. One of the curves was reversed at 70  $\mu$ N to 25  $\mu$ N and reloaded to exhibit a lower pop-in load and reduced pop-in displacement; compare with the elastic and plastic displacements shown in Fig. 9(a). The comparison of curves shown in Fig. 23 demonstrated that a certain amount of plastic deformation could occur during otherwise essentially elastic loading, and that this should be taken into account in fitting to the Hertzian loading equation. Attention was directed to blunting of the indenter tip during repeated loadings and to other experimental and dislocation model considerations [94].

Fig. 23. Load-displacement curves for a (111) Ni crystal surface [94].

Zhong and Zhu employed an interatomic potential in a finite element description of homogeneous nucleation of dislocations for (111), (110) and (100) crystal surfaces of aluminum, copper and nickel crystals [247]. Fang, Chang and Huang reported MD results for aluminum. Also finding, as Zhong and Zhu had done, that nucleation, gliding and interaction involved Shockley partial dislocations [248]. Tsuru, Shibutani and Kaji also investigated the behavior of aluminum, in their case, with the embedded atom technique and produced simulated images accomplished with the visualization software ATOMEYE [249]. Emphasis was given to needed critical resolved shear stresses being higher than the theoretical shear strength because of the compressive stress state underneath the indenter. Their model load – displacement curves for aluminum show the same type of relative elastic and pop-in displacements as shown in Fig. 23.

As an example case for body-centered cubic metals, Alacala, Dalman, Franke, M. Biener, J. Biener and Hodge have reported simulated dislocation structures at nanindentations in tantalum crystals [250]. Figure 24 shows an early result of two dislocation loops spreading from underneath an impressed spherical indenter for incipient plasticity that nevertheless has involved rather complex pre-slip very fine scale twin nucleation and interaction plus annihilation to produce the loops. The leading edges of the loops are in edge orientation. Twin elimination has been attributed to reduction of stacking fault energy for twin layers thinner than four atomic layers and found to be enhanced at higher temperatures and decreased loading rates. Sectional views have been shown of the progressive development of dislocation loops and their interactions.

Fig. 24. Dislocation nucleation at an MD-modeled pop-in event in tantalum [250].

The cumulative dislocation-based mechanisms have led to the determination of load-displacement curves for (111), (011) and (001) crystal surfaces at the different temperatures of 296 and 473 K while such results were simulated via MD at 77, 296, 473, and 900 K. The MD model description of dislocation nucleation, involving a combination of shear stresses and pressure under the rounded tip Berkovich indenter, proceeds onward from the single dislocation stacking faults and multiple atomic layer twins being nucleated and annihilating to form a resultant slip-type of dislocation loop structures that is shown in Fig. 24 to produce the results shown in Fig. 25. Model descriptions based on indenter tip  $D$  values of 24 and 48 nm produce a similar trend of pop-in measurements to that shown experimentally in Fig. 25 with  $D = 380$  nm. The current observation of the importance of a pressure effect in this bcc case is in agreement with the conclusion reached by Tsuru *et al.* [249] for their fcc case of aluminum.

Fig. 25. Orientation dependent Berkovich indentations curves for tantalum [250].

Other aspects of atomic model computations have involved considerations of the relationship between hardness and atomic bond parameters [251, 252], in extension of early work by Gilman [173-175], and to modeling the influence of indenter shape [253]. Particular aspects of atomic modeling have entered into practical considerations such as nanohardness aspects of steel surface treatments [254]. A quantum mechanical study of solid solution effects on nanohardness has been reported [255]. Microstructural aspects of nano-twinning on hardness have been assessed [256]. An advantage of strain gradient plasticity for simulation of microhardness has been presented [257], as originally employed in the ISE model description developed by Nix and Gao [56].

### 3.2.2. Crystal hardness and plastic anisotropy

After Knoop's development at the U.S. National Bureau of Standards of the exaggerated 7/1 length ratio for a diamond indenter shape for investigation of orientation-dependent plasticity measurements in metal and mineral systems [258, 259], Daniels and Dunn developed a remarkable geometrical analysis for explaining the orientation dependent anisotropy of hardness measurements in metal crystals [260]. The model description was based on achieving the critical resolved shear stress for particularly favorably oriented crystal slip systems. The topic of anisotropy brings together the subjects of crystal mechanics and continuum plasticity and involves results obtained, and continuing to be obtained, on all types of crystals and textured polycrystal and/or polyphase materials.

Brookes, O'Neill and Redfern [261] produced an updated description of the Daniels and Dunn analysis with addition of a minor modification based on their own crystal anisotropy measurements. Armstrong and Raghuram [211] also re-examined the Daniels and Dunn analysis with conclusion that two orientation dependencies of crystal yielding and work hardening should be involved in determining the crystal hardness anisotropy. Evidence for such consideration was provided by Calder and Armstrong [262] in accounting in terms of increasing work hardening for the greater Knoop anisotropies reported for aluminum, copper and nickel crystals, respectively.

Noteworthy assessments of different crystal hardness anisotropy measurements have been reported by Brookes [263], Sargent and Page [264]. Individual crystal anisotropy measurements and analyses have been obtained on many crystals, including the following ones: calcium fluoride [265]; calcium and sodium nitrate [266]; MgO [267]; LaB<sub>6</sub> [268]; energetic (explosives) [269]; anthracene [270]; rare earth garnets [271]; magnesium sulphate hepta-hydrate [272]; gamma-TiAl [273]; and, a nickel base superalloy [274]. A result from the latter reference is shown in the square-framed spherically-modified indentation of Fig. 26.

Fig. 26. Plastic anisotropy at a spherical indentation made on an fcc Ni-based superalloy CMSX-4 crystal (001) surface [274, 275].

The indentation shape in Fig. 26 was accounted for in a finite element simulation that took into account the deformation gradient accompanying the indicated discrete slip band displacements. The overlap of surface pile-up/sink-in displacements was mainly attributed to the anisotropic crystal strain hardening property. Such sink-in description presumably relates to screw dislocation activity of the type described for the special situation involved in accounting for the anisotropic shapes of [100] and [110] direction-aligned diamond pyramid indentation patterns observed on an (001) MgO crystal surface [131]. Further analysis related to Fig. 26 was presented in a follow-up detailed description of pyramidal indentations given by Eidel [275]. The over-riding influence of the geometry of the discrete crystal slip systems was confirmed in the finite element simulation and convex or concave shapes were confirmed depending on the relative orientation of the indenter and, again, emphasis was given to the importance of the crystal strain hardening property.

Additional concerns for hardness anisotropy occur for textured polycrystal or polyphase or composite materials. Thus the truncated spherical indentation shape of Fig. 26, that involves greater indentation displacement in <110> directions orthogonal to the easily-observed slip band traces relates to a similar observation and indentation spread along a direction perpendicular to aligned grain boundaries in an Al-Li 2090-T8E41 alloy [276]; see reference [52]. Other related observations apply for anisotropy of indentations in a SiC-reinforced aluminum alloy [277] and a magnesium alloy [278].

### 3.2.3. Polycrystal/polyphase plasticity

Hall proposed that the hardness dependence on polycrystalline grain diameter,  $\ell$ , should follow a similar dependence to that observed for the yield point [279], which dependence is now known as the Hall-Petch (H-P) relationship and is known to apply generally to the full tensile or compressive stress-strain behavior of polycrystals [280] as

$$\sigma_{\varepsilon} = \sigma_{0\varepsilon} + k_{\varepsilon} \ell^{-1/2}. \quad (16)$$

In Eq. (16),  $\sigma_\epsilon$  is the unidirectional flow stress at a constant value of strain,  $\epsilon$ , and  $\sigma_{0\epsilon}$  and  $k_\epsilon$  are experimental constants. Thus, the counterpart hardness dependence is expressed as

$$\sigma_H = \sigma_{H0} + k_H \ell^{-1/2}. \quad (17)$$

Comparative experimental evaluations of Eqs. (16) and (17) have generally assumed that  $k_H \approx 3k_\epsilon$  and  $\sigma_{H0} \approx 3\sigma_{0\epsilon}$  although there is a question about the appropriate value of  $\sigma_{0\epsilon}$  to be employed in the relationship.

Fig. 27. A Hall-Petch dependence for the hardness of  $\alpha$ -brass [281].

Armstrong and Jindal [281] found historical evidence for the validity of Eq. (17) in a 1919 study by Bassett and Davis [282] describing Brinell hardness measurements obtained on two recrystallized cartridge brass materials over a range in grain sizes. The data are shown in Fig. 27 on an H-P basis in comparison with a parametric equation proposed in 1919 by Mathewson [283] and in comparison with other results on 70 – 30  $\alpha$ -brass reported more than 40 years later by Bassett and Rhines [284]. Much later measurements made on the same basis of studying recrystallization, this time of  $\alpha$ -titanium material by Cline and Hu [285], were also shown by Armstrong and Jindal [286] to follow Eq. (17) over a very large range in grain size. Jindal and Gurland extended the H-P hardness relationship to include taking into account particle effects for tempered and spheroidized carbon steels [287].

The grain size dependence of hardness for fcc metals, akin to the lesser grain size dependence observed for the conventional stress – strain behavior [280], has been an active area of research. Lim and Chaudhri have reported on the nanohardness of high-purity copper and aluminum materials and concluded, from comparison with single crystal values too, that the dislocation density was probably a more important factor in determining the behavior of purer material [288]. Lim and Chaudhri displayed their results on an effective stress – strain basis in line with Tabor’s analysis [38]. In an important series of articles, Hou and colleagues have investigated the effect of spherical indentation size and H-P dependence for annealed copper polycrystals [289-292]. Figure 28 shows a result obtained with employment of different ball sizes applied to a large range in grain size in different materials [289].

Fig. 28. Hall-Petch dependence for copper employing different ball sizes [289].

A principal concern for Hou and colleagues was to take proper account of an ISE at the different indentation size and grain size measurements. H-P behavior was verified for a ratio of grain diameter to projected diameter of contact area,  $d$ , less than a factor of 6. At larger ratios, the H-P dependence is observed to be superposed on the ISE. From the slope of the linear H-P dependence in Fig. 28, and taking  $D = \ell$  in Eq. (17),  $k_H \approx 18 \text{ MPa}\cdot\text{mm}^{1/2}$ , and  $k_H/3 = 6 \text{ MPa}\cdot\text{mm}^{1/2}$  in agreement with a reported  $k_e \approx 5 \text{ MPa}\cdot\text{mm}^{1/2}$  for copper unidirectional stress – strain behavior [280, 293]. In reference [292], Hou and Jennett provide a simulation of combined ISE, H-P, and dislocation density influences on determination of  $k_e$  for copper. Konstantinidis and Aifantis have assessed the grain size dependence of hardness on a rule of mixtures approach for nanopolycrystalline metals and intermetallics in order to account for a reversal from H-P behaviour at very small grain sizes [294]. The normal H-P division of strength into “grain volume” and “grain boundary” regions was also separated in the model analysis. Additional consideration was given to the presence of a grain boundary “width” and to the occurrence of grain “triple junctions” in accounting for the resultant properties.

Other researchers have directly measured the hardness near to or directly at the grain boundaries. Eliash, Kazakevich, Semenov and Rabkin investigated the nanoindentation hardness of grain boundaries and their triple junctions in molybdenum tri-crystals [295]. An increased grain boundary hardness of ~30% was attributed to the boundaries being a barrier to nucleation of dislocation loops. Ohmura and Tsuzaki employed nanoindentation hardness testing on interstitial-free iron material to show that the grain boundary could initially be a source of dislocations and then subsequently act as a barrier to motion [296, 297]. Iron carbide films at the boundaries in a tempered Fe-C martensitic steel were shown to increase the H-P  $k$  value. Large pop-in displacements measured for the steel were associated with greater grain boundary hardness and analyzed in terms of the Hertzian description of stresses. Britton, Randman and Wilkinson measured the nanoindentation pop-in characteristics of grain boundaries in a Fe-0.01% C steel also to investigate the transfer of intragranular slip [298]. Such boundary-associated pop-ins were not observed for the cold-worked material nor for interstitial-free iron or for pure copper, thus leading to the conclusion that the (Cottrell-Bilby) mechanism of interstitial pinning of dislocations at or near the grain boundaries in steel was responsible for the H-P dependence as originally concluded by Hall and Petch. An effect of grain boundaries on the nanoindentation hardness of (bcc) iron, molybdenum, tungsten and tantalum materials was reported by Voyiadjis, Almasri and Park [299] in a study employing a Berkovich indenter and a continuous stiffness measuring procedure, also including consideration of a strain gradient mechanism approach to evaluating the hardness on a simple power law basis.

The nanoindentation of fcc metals was also investigated in the same manner described for the bcc metals by Almasri and Voyiadjis, in this case, for silver, copper, aluminum, lead and nickel materials [300]. Qu and Zhou have reported atomistic MD simulations of twin boundary hardening measured by nanoindentations in copper [301]. Zhang, Ohmura, Emura, Sekido, Yin, Min and Tazaki reported on the nanoindentation hardness of ultra-fine grain aluminum [302] which study may be contrasted in terms of hardness level and importance of the H-P grain size dependence with results reported on nanopolycrystalline diamond by Sumiya and Irifume [303] and by Gao [304]. And for a relatively hard

material, smaller grain size association with greater hardness was reported in an evaluation of titanium nitride films produced by plasma nitriding on the surface of Ti-6Al-4V material [305].

Figure 29 shows combination of ISE, H-P and specimen size aspects in an important investigation of nanoindentation measurements obtained by Bull, Sanderson and Oila on submicrometer copper thin film materials [306]. First note the ISE-affected indentation depth influence on the levels of the hardness stresses. An increase of more than a factor of 2 occurs for the apparent hardness of an individual crystal (grain). The ISE was evaluated in line with the model proposed by Nix and Gao [56]. Secondly, there are the H-P dependencies shown at the smaller grain sizes leading to a  $k_H \approx 21 \text{ MPa}\cdot\text{mm}^{1/2}$ ; see Fig. 28 and

Fig. 29. Indentation size, crystal size, and Hall-Petch effect for copper [306].

the evaluation of  $k_H \approx 16 \text{ MPa}\cdot\text{mm}^{1/2}$ , thus giving a result perhaps increased a bit by a continuation of ISE influence. And thirdly, there is the transition from individual crystal hardness to polycrystal hardness that Bull *et al.* associate with a need for 6-10 grains to be included within the plastic zone of the indentation in order to show H-P behavior. The effect is suggested to be an analogous to the “specimen size” effect described for a tensile test in which  $\sim 20$  grains through the thickness were proposed to be needed for measurement of a reliable H-P dependence [307].

Fig. 30. Hardness of WC-Co composite with Hall-Petch dependences for the constituents [309].

Lee and Gurland provided valuable extension to understanding the hardness properties of composite WC-Co materials by employing an H-P model description for the individual phase components in combination with a “rule of mixtures” relationship for the amount of each phase [308]. Thus, the relationship is obtained for the composite hardness,  $H_C$

$$H_C = H_{WC}V_{WC}C + H_{Co}(1 - V_{WC}C). \quad (18)$$

In Eq. (18),  $H_{WC}$  represents the WC phase and  $H_{Co}$  for the cobalt phase, each having their own H-P dependencies,  $V_{WC}$  is the volume fraction of the WC phase, and  $C$  is the contiguity parameter to take into account the WC-to-WC particle contacts. Figure 30 shows the Lee and Gurland (open circle and cross) points that led to development of Eq. (18) and also includes a graphical method of assessing the relative contributions made by the H-P,  $C$  and  $V_{WC}$  factors in determining the overall hardness of the composite [309]. The figure includes added triangle measurements reported by Richter and von Ruthendorf [310] Figure 30 was originally plotted by Lee and Gurland with only the open circle and cross points showing separate “rule of mixtures” dependencies on the carbide volume fractions obtained for the two particle sizes. In the current figure, three of those points, composed of two open circle ones and a cross one, have been shifted to an effective volume fraction value,  $V_{WC}^* = CV_{WC}$ , and matched with the linear dependence in Eq. (18) based on  $V_{WC}^*$  and connecting to the H-P measurements plotted on the ordinate axis for each phase. The Lee-Gurland model relation seems to fit the experimental results quite well as may be compared with a semi-empirical description provided for the same and other hardness results analyzed by Makhele-Lekata, Luyckx and Nabarro [311]. A review of these results and other hard material results has been provided by Armstrong [312].

Nanoindentation testing has been applied to a number of nanocomposite materials, for example, as described by Aldousiri, Dhakal, Onuh, Zhang and Bennett [313] for layered silicate-filled spent polyamide materials. Structural characterization was accomplished with application of XRD, TEM and SEM techniques in providing analysis for the improved nanohardness and moduli values that were achieved. Another example has been provided by Shao, Zbib, Mastorakos and Bahr on model development of spherical nanoindentations made on nanoscale multilayered metallic (NMM) composites of copper-nickel, copper-niobium and copper-nickel-niobium compositions [314]. Various single crystal layers of the different material combinations at nanometer thicknesses were constructed in the model system and indented with spheres also of nanometer diameters. Known orientation relationships were employed for the

Fig. 31. Spherical indentation of multi-layers [314].

interface structures between the crystal layers. A power law relationship, using the Tabor relation for effective strain in Eq. (13), was employed to characterize the plastic stress-strain dependence that was monitored as it progressed through the stacked layers. Simulation of the load - depth dependence showed discrimination between piling-up, as for the copper-nickel case, vs. sinking-in for the copper-niobium case. The dislocation densities generated in the different cases were also monitored and led to the qualified conclusion that the composite strength followed an inverse power law dependence on the layer spacing. Figure 31 shows some results for each of the four cases. The  $\lambda$  parameter marked in each inset snapshot measures the (CuNi) pile-up or (CuNb) sink-in and was utilized as a gauge against the plastic penetration depth. The lower left snapshot corresponds to a layers of 5 nm thickness indented with a sphere of radius  $r = (D/2) = 6$  nm while the snapshot in the lower right corner involves 2 nm thick layers at the given  $r$  value. Partial dislocation Burgers vectors were identified at the initial stages of nucleation and were observed to form unit dislocations by various reactions.

### 3.3. Cracking and indentation fracture mechanics

Cracking at hardness indentations is of interest for reason of understanding the two aspects of how cracks are initiated by dislocation plasticity and how cracks propagate. Figure 32 is an AP crystal example [185].

Fig. 32. Slip-initiated cracking at plane intersections in AP (ammonium perchlorate) [185].

In Figure 32, slip on intersecting  $\{111\}$  slip planes is clearly delineated and has produced a  $(-210)$  cleavage crack on the top-side of the aligned indentation. Additional plasticity was prompted by the crack initiation and so the top of the residual indentation is seen to be elongated in the  $[-1-20]$  direction. Such a result follows on from the early observation by Keh [190] of intersecting slip systems at indentations in MgO crystals and dislocation activity on them, for example, as described for the diamond pyramid indentation in Fig. 13. Keh, Li and Chou [315] developed a dislocation pile-up model for the  $\{110\}$  type cracking that is observed in MgO. And in a follow-up report, Chou, Garofalo and Whitmore provided an evaluation of the intersecting slip band pile-up model on a dislocation mechanics basis [316]. Gaillard, Tromas and Girard provided a quantitative description of dislocation pile-ups produced at the indentations in MgO [317]. Armstrong and Elban presented a 3-D model description of the crack-forming dislocation interactions for an aligned diamond pyramid indentation. [318]. Chaudhri has commented on the model considerations in light of his own experimental results obtained with a spherical indenter [319]. Related dislocation model results were presented for MgO [320] and for cubic zirconia [321] crystals.

The nucleation of cracks at dislocation pile-ups is dependent on the indentation size and hardness stress. Figure 33 shows a comparison of plasticity and predicted or observed cracking results determined for RDX and NaCl crystals [52]. First, consider the open square points obtained for an RDX crystal indented with a 1.59 mm diameter steel ball. The individual microhardness measurements demonstrated even for the relatively brittle RDX crystal that dislocation plasticity preceded cracking that, in turn, was initiated more easily than was predicted by the open circle point on the dashed elastic loading line. The terminal open circle point was calculated on the basis of Eq. (11) for the indentation fracture mechanics prediction of elastic loading proceeding directly to the hardness cracking stress [27]. The nearby solid line shown in Fig. 33 for RDX results reported by Ramos, Bahr and Hooks, involving continuous loading of a rounded tip Berkovich indenter with  $D = 2.96 \mu\text{m}$  and different elastic modulus, was obtained for different surface treatments on a same RDX crystal surface [320]. No cracking occurred in analogous comparison of cracking being absent for MgO between the lower load case of Fig. 9(c) and higher load case of Fig. 13. In further comparison between the RDX and more ductile NaCl crystal result also obtained with a 1.59 mm diameter ball, such ductility for NaCl was explained in terms of slip occurring on  $\{111\}$  planes [131].

Fig. 33. Absent cracking in nanoindentation tests on RDX [52].

Also in contrast to the old-time consideration that the occurrence of cracking at an indentation site would invalidate the hardness measurement, the development of indentation fracture mechanics by Frank and Lawn [20] has established connection with the Griffith theory for crack propagation in a gradient stress field, thus leading to characterization of crack surface energy and indentation fracture toughness stress intensity values, in the latter case, shown to agree with conventionally determined measurements [310]. Hagan and Chaudhri [321] used Eq. (10) to determine surface energy values for RDX that were shown by Elban [324] to be just larger than the thermodynamic value, thus giving indication of only a small plastic strain contribution to crack growth. The determination of the surface energy in Eq. (10) comes from the predicted  $(3/2)$  power of the slope of  $\log P$  plotted vs. the crack size. Figure 34 is a comparison of the load dependence of diamond pyramid indentation diagonal length and tip-to-tip crack length measurements made across the indenter diagonal directions, as compiled by Armstrong and Elban for microhardness indentations put into MgO and RDX crystal surfaces [325]; the references included in the figure are [213], [323], [214], and [326] in order of their appearance.

Fig. 34. Indentation size and crack size dependences for MgO and RDX [325].

The comparison of the quite different results for the two crystals in Fig. 34 shows that the cracking of MgO controls the hardness value whereas the reverse situation applies for RDX, that is, crack growth for RDX is apparently determined by the very small amount of plastic deformation occurring at the crack tip. Armstrong and Elban have related the results in Fig. 34 to other deformation characteristics of RDX [327]. Dong, Huang and Kang, have extended the study of (001) crystal indentations in MgO to observations made on {110} plane indentations [328]. Lin, Chu and Lee have considered such measurements in relation to a brittle to ductile transition in behavior [329]. Yan and Zhou have looked into dislocation nucleation under a sharp tip indenter with regard to consideration of cracking [330]. And Thallidi, Schwartz, Phend, Hutchinson and Whitesides have looked into simulation of indentation fracture as a problem of mesoscale self-assembly [331]. Armstrong has pointed to the relationship between the H-P grain size dependence and that originally ascribed to the Griffith analysis for an inverse square root of crack size dependence for the brittle fracture stress thus leading to an H-P type dependence for the conventional and indentation fracture mechanics stress intensity [332]. Such dependence was found for indentation fracture mechanics measurements reported for the WC-Co system in [309] and in assessment of measurements reported for alumina materials [333, 334].

As for diamond, the issue of whether ambient temperature plasticity occurs during indentation of silicon crystals vs. the alternative of an immediate onset of cracking is an important topic and with additional concern for the role of a phase transformation also occurring during indentation [168]. Apparently, the two behaviors are very close in terms of the required indentation stress. Atkinson et al., in addition to assessing the indentation fracture mechanics aspects of the different indentation-related crack geometries [23], performed their own measurements on silicon under a Berkovich nanoindenter. Direct observation with a focused ion beam system of a rather large well-defined residual nanoindentation created at ~110 mN was required to produce three median cracks extending from below the indentation tip to just past the surface projected indenter diagonal lengths. Wan, Shen, Q. Chen and Y. Chen have reported a finite element analysis of such cracking too on the radial, median, lateral and half-penny cracks [335]. Figure 35 shows an earlier compilation of results obtained on silicon crystals by Armstrong, Ruff and Shin, including their own measurements [336]. The log/log representation of the data includes a slope of 3 for the elastic behavior, 2 for the plastic hardness, and (3/2) for an indentation fracture mechanics dependence. The influence of the ISE is seen in the elastic/plastic regime and also carrying over to the low-load cracking behavior. As referenced above in connection with the pioneering ISE measurements in nanoindentations, cracking was absent in the results reported by Pethica *et al.* [55]. Cracking was estimated to occur first at ~30 mN, thus in reasonable agreement with the minor appearance of cracking at the higher load of ~110 mN specified by

Atkinson *et al.* [23] and with a  $[\log P/\log c]$  type plot of diamond pyramid measurements obtained by Wan *et al.* [335]. No obvious indication of any effect of phase transformation presents itself in Fig. 35.

Fig. 35. Elastic, plastic, cracking load dependence for silicon [336].

However, in line with the above-referenced measurements reported by Minor *et al.* [232] and by Nowack *et al.* [234], it seems reasonable that close availability of a free surface would favor easier dislocation nucleation over cracking or any need for transitional phase transformation to effect formation of a fully plastic indentation.

Sangwal has presented a review of ISE and cracking behaviors in relation to microhardness measurements obtained on brittle crystalline materials [337]. Yan and Zhao [338] have assessed the dislocation nucleation problem in connection with possible cracking behavior. Armstrong, Ferranti and Thadhani [334] have considered further the elastic, plastic and cracking behaviors for especially hard crystalline materials. Relatively brittle aluminum oxynitride [339] and  $\text{Cu}_6\text{Sn}_5$  intermetallic [340] materials have been investigated. Clough and Wadley obtained indentation fracture mechanics  $K_C$  values and acoustic emission measurements for the industrially important A533B nuclear pressure vessel steel. [341]. Connection of hardness with cohesive energy of a material has been investigated by Roberts and Rowe for pharmaceutical compaction of crystals [342]. Also, there is very broad interest in indentation cracking behaviors associated with brittle glassy materials, for example, beginning with relationship of indent pre-cracks to the overall fracture behavior [343].

#### 4. Amorphous and polymeric materials

Two issues of major concern that emerge from hardness testing of amorphous materials are the increased local densification of the material at residual indentation sites and, separately, the nature of crack-initiated shear band structures accompanying permanent deformations. Yoshida, Sawasota, Sugawara, Miura and Matsuoka [344] have reported on the effect of indenter geometry on indentation-induced densification of soda-lime glass. And, Kato, Yamazaki, Itakura, Yoshida and Matsuoka [345] investigated densification under a diamond pyramid indenter for several glass materials in relation to their markedly different susceptibilities to crack initiation. The densification was measured via AFM examination before and after post-indentation annealing treatment. Early work on microhardness aspects of glass materials had been reported by Mackenzie, first with Neely [346], and then with Yamane [347]. Hagan continued from the

hardness report done with Chaudhri on RDX and PETN energetic crystals [323] with reports on the hardness of fused silica [348] and soda-lime glass [349]. Another report on soda-lime glass by Gorham, Salman and Tan describes the failure sequence observed on unloading [350]. Iwashita, Field and Swain [351] describe the indentation hysteresis for glassy carbon material. More recent test results have been reported, first by Smedskjaer, Mauro and Yue [352], and then by Smedskjaer, Mauro, Sen, Deubener and Yue [353] with the aim of predicting hardness properties based on relation of the network topology as modified on the surface of the glass through diffusion of individual atomic species.

Comparison of crystal and metallic glass results has been investigated in nanoscale structural and test results and interpretations reported by Packard, Frank, Homer and Schuh [354]. Perhaps surprisingly, these authors report smaller strain rate and temperature dependencies for the glass material tested far below its transition temperature. Computer modeled results are presented for a “nanoscale strength distribution” explanation of the nanoindentation measurements. As mentioned above, Torres-Torres, Munoz-Saldana, Gutierrez-Ladron-de-Guevera, Hutado-Macias and Swain [62] have provided nanoindentation test results and FE simulation of them for fused silica material.

Yoo and Jang have obtained Fig. 36 in a macro-scale study of various stages of sub-surface shear banding achieved in spherical indentation tests of a split-specimen Zr-based metallic glass material [355].

Fig. 36. Shear band structure observed on the post-bonded centerline interface of a Zr-based metallic glass at several stages of indentation with a WC sphere with  $D = 1.0 \mu\text{m}$  and applied loads of: (a) 19.6, (b) 49, (c) 98 and (d) 196 N [355].

Continuous loading curves were measured in obtaining the sectional views presented in Fig. 36. The sub-surface shear banding morphology revealed in each sectional view was gently eliminated by polishing and then probed with a square pattern of nanoindentations spaced at  $\sim 25 \mu\text{m}$  separation and covering the deformed cross-section. The extent of the shear bands was analyzed on the basis of a Hertzian description. The deformed region was softer than the region outside of the deformation zone and attributed to the shear bands being softened. The softened shear band result was confirmed in a follow-up study by Yoo, Kim, Oh, Ramumurthy and Jang, including additional confirmation that the inter-shear-band regions were also softer. [356].

The results of Yoo *et al.* were analyzed in detail by Chen and Lin [357] in terms of primary and secondary shear band activity being basically responsible for the overall deformation response of the material. Figure 37 shows the schematically the modeled pattern of primary and secondary shear bands.

Fig. 37. Model description of primary and secondary shear band structures [357].

Chen and Lin present an instructive free-body diagram of the computer-simulated loading system applied to an elemental shear band annulus. The stress state consists of a hydrostatic core positioned immediately below the penetrating spherically-tipped indenter interfaced by an encompassing state of shear. Connection was made with the cavity expansion model of Johnson, see book listing in Table 1, and with slip-line field patterns developed in plasticity theory [358]. Characteristics of the primary and secondary shear bands, such as radii relationship, center positions, radii ratios, as well as the ratio of indentation radius to indenter diagonal length were enumerated. The Chen and Lin results relate to a description by Zhang, Jing, Subhash, Kecskes and Dowding [359] of primary, secondary and tertiary shear band structures, also involving predictions obtained from modification of the expanding cavity analog.

Other reports on nanoindentation aspects of shear banding were reported by Greer, Castellero, Madge, Walker and Wilde who also studied the behavior of partially devitrified material [360]. Pan, Yokoyama, Fujita, Liu, Kohara, Inoue and Chen provided a correlation between measurements of structural relaxation obtained by annealing and reduction in size of the shear transformation zone accompanied by an increase in density [361]. Paduraru, Andersen, Thyssen, Bailey, Jacobsen and Schiotz modeled shear band formation of nanometer widths with atomic scale simulations and drew comparison with simulation of dislocation avalanches in nanopolycrystalline material [362]. For the case of a sharp indenter, Conway and Kirchner related shearing behavior to the onset of fracturing [363].

## 5. Deformation rate effects

The viscoelastic indentation behaviors of silicate glasses have been reported on by Sakai, Shimizu and Ito [364]. Misra, Sohn, W. Kim and D. Kim have dealt with plasticity aspects of rate-dependent serrated flow observed for a bulk metallic glass [365] and dynamic indentation deformation aspects of a chemically strengthened glass have been described by Jannotti, Subhash, Ifju, Kreski and Varshneya [366]. An interesting approach in terms of interpretation of results has been reported by Liu, Z. Wang, Peng, Yu and W. Wang [367]. They have utilized a “flow unit” model to describe anelastic and plastic deformations determined in the relaxation behavior of cyclic hysteresis measurements made on two metallic glass materials. The “flow unit” designation is reminiscent of the historical application made by Kauzmann of chemical reaction rate theory to the deformation rate dependence of plasticity in metals [368]. Armstrong and Walley have reviewed the subject as related to the high rate deformation behavior of metals [369]. An important parameter in the rate theory is the activation volume,  $v^*$ , that is determined from the product of Boltzmann’s constant, the temperature and the logarithmic dependence of the strain rate on shear stress.

Walley and Field [370] have reported extensive measurements for a number of polymeric materials of the dependence of stress on the natural logarithm of the strain rate. Chen, Wang, Huan and Luo have investigated the viscoelastic behavior of polymer-based materials [371]; and relating to the preceding work in [79], Pelletier et al. have reported also rate effects and relaxation measurements for spherical indentation of glassy polymer materials [372].

The foregoing references on rate dependence of hardness determinations for glassy ceramic and polymer materials give an indication of progress made from the early 20<sup>th</sup> century with metal deformations in mind, for example, involving the pendulum hardness test of Herbert [373] and reported time dependence of hardness measurements reported by Hargreaves [374]; see also Walley [1]. A particular interest in metals at the present time is to look into hardness testing for the purpose of developing constitutive relations for use in material dynamics calculations, particularly under dynamic loading conditions so as to relate to material penetrations; see [163-170]. In addition to previous work mentioned above [164, 165], Sundararajan and Tirupataiah have produced a pair of articles on dynamic indentation loading and analysis of results [375]. Wu, Fang, Kim and Lee [376] have presented an interesting application of such analysis to high speed impact behavior exhibited by aluminum particles thrown onto a steel substrate in a coating operation, seen to be under less severe condition of mass effect than that described by Murr [167] for penetration of copper by an aluminum sphere.

Almasri and Voyiadjis describe measurements for the strain rate dependence of hardness for a copper and a 1018 steel material [377]. Reference was made earlier to their article with Park on nanoindentation results for the bcc metals: iron, molybdenum, tungsten, and tantalum [299]. Xu, Yue and Chen [378] have characterized the strain rate sensitivity of polycrystalline copper in terms of  $v^*$  measurements determined in indentation relaxation experiments. Such measurements relate as well to creep deformation rate experiments at the other end of the strain rate deformation spectrum. A review of his own pioneering work on indentation creep had been given by Li with emphasis given to the ability of performing small scale testing [379]. Choi, Yoo, Kim and Jang [380] have re-visited the topic. Shalaby has reported microhardness creep results on alloying of rapidly solidified tin-zinc solder materials [381]; see the nanoindentation results of [157]. Somekawa and Mukai have reported on nanoindentation creep measurements made separately on grain interiors and at more strain rate sensitive grain boundaries in magnesium [382]; see [294-298]. Yokouchi, Chou and Greenfield [383] used repeated indentation testing of copper with spherical and cylindrical indenters and finite element modeling to characterize the deformation behavior. Basu, Radovic and Barsoum investigated the time dependent nanoindentation hardness of ZnO (11-20) crystal surfaces [384]. A power law dependence was obtained for the time dependence of hardness and explained in terms of dislocation pile-up activity on the basal (0001) planes; see Fig. 12 and reference [98].

As indicated earlier for a KCl crystal, Chaudhri has given in his review of indentations and dislocations, a description of early results obtained on rate dependent spherical indents under essentially static loading and in impacts [168]. The initiation of cracking was directly observed via TEM imaging. For the gradual spherical loading of an MgO crystal (001) surface, a series of micrographs was produced that optically tracked the loading behavior for larger ball size and consequently larger load over very nearly the total range of behavior described here between Figs. 9 and 13 for the respective references [57] and [132]. Clear delineation of slip band structures within the encompassing picture-frame structure was observed after the central indentation appeared as a shatter zone of multiple cracks. Dynamic tests involving 700  $\mu\text{m}$  spherical diameter WC at 145 m/s impact on the (001) surface of a KCl crystal were also sequentially photographed with a high speed camera with sub-unit  $\mu\text{s}$  frame sequencing capability. Chaudhri employed the results to derive an operative shear stress that then was correlated with estimations of a linear dependence of dislocation velocity.

Dynamical aspects of  $\langle 100 \rangle$  dislocation lines at indentations made on MgO {100} crystal faces have been mentioned [183]. Williams, Armstrong, Dick, Jorgensen and Wu [385] made a comparison of both hardness and crack size dependencies measured in dropped ball experiments done on the same type MgO crystal surfaces as for the static measurements that were previously described [325]; see Fig. 34. Results from Rickerby and Macmillan [130] and Chaudhri, Wells and Stephens [386] are included in the figure.

Fig. 38. Static and dynamic MgO crystal indentation measurements [385].

An increased hardness at greater applied strain rate is seen by comparison of the topmost filled square and filled triangle points plotted in Fig. 38. The corresponding match of radial crack lengths shows an even greater effect of the strain rate.

## 6. Applications

The foregoing compilation of references and brief descriptions of them, while only covering a limited number of topics pertinent to hardness and hardness testing, provides evidence for the opening statement that one cannot hope to cover all aspects of the combined subjects. The situation is more true for all of the applications of hardness testing. Here we mention only a few items that seem pertinent to the many application type topics.

### 6.1. Quality control and ceramics

As an example of the continuing progress in updating engineering standards, there is the recent note provided by Tobolski concerning the purview of ASTM on the subject [387]. A practical example of updating test equipment or methods of performing hardness tests is given in the report by Baxevari and Giannakopoulos [388], this consideration relating to some extent to the report by Schindler [88]. It is probably safe to say that more hardness testing is done on ceramic materials than on any other type of material. Some evidence for this assertion comes from the results that have already been described. General coverage of the hardness considerations for ceramics is provided in reports by Roberts [389] and by Leavy, Brannon and Strack [390]. Krell and Schaedlich [391] have described interpretation of ceramic hardness measurements on a depth-sensing basis. Nanoindentation size effect issues for initiation of plasticity have been described by Zhu, Bushby and Dunstan [392]. A particular case of investigating the damage tolerance of ceramic  $Ti_3SiC_2$  material has been reported by Kooi, poppen, Carvlho, Ed Hossen and Barsoum [393].

### 6.2. Thin films and coatings

The topic of thin films and coatings deserves particular attention because of the physical condition of such materials are ideally suited to hardness testing of their mechanical properties. Important experimental results and interpretation have been provided by Doerner and Nix [394]. Yu, Sanday and Rath have provided an important elastic model description of flat, conical and spherical indentation hardnesses [395].

Fig. 39. Schematic diagram and parameters for flat, conical and spherical indentation of thin films [395].

In [395], graphical results are presented for the contact area and load dependencies on penetration depth for the film taken as an elastic layer either in frictionless contact or perfectly bonded onto a semi-infinite elastic half-space. Kulchitsky-Zhyhailo and Rogowski [396] have evaluated the stresses for a hard coating on a layered elastic half-space. Emphasis is given to the important ratio of layer thickness and contact area.

Chicot, Gil, Silva, Roudet, Puchi-Cabrera, Staia and Teer have reported a method for determining thin film hardness by means of modeling the indentation loading curve [397]. Figure 40 shows one reported result. The figure shows the loading curve result for a rather complex diamond-like carbon coating

Fig. 40. Relationship of loading dependencies for limiting film and substrate hardnesses [397].

of 2.55  $\mu\text{m}$  thickness and measured 0.063  $\mu\text{m}$  roughness put onto a 316L stainless steel substrate. Such films generally exhibit diamond pyramid (Vickers) hardnesses in the range of 20 to 40 GPa [397]. The limiting parabolic dependencies shown for the film and substrate apply for a constant hardness value; see Fig. 4 of reference [95]. The quantities,  $P_0$ ,  $H_0$  and  $H_{LSF}$  are correction factors introduced for zero contact load and ISE corrections employed after the method of Nix and Gao [56]. Such load-penetration depth measurements were carried through to counterpart hardness vs. relative indentation depth curves, again, shown to be contained within the limiting hardness values of the film and substrate material. There is the relationship of the results to the MD simulations reported by Solar *et al.* [246]. The hardness of ultra-thin-

films has been characterized by Gitis, Vionogradov, Ilja and Kury for relationship to tribological properties [398].

Jaffar [399] has provided prediction of film thickness taken as a soft layer being squeezed by rigid spherical impression being made onto a rigid foundation. There is connection with lubrication of a synovial (bone) joint. The topic is only slightly removed from a coupled pair of articles by McCarthy, Hussey and Gilchrist [400] on the sharpness of straight edge blades assessed in terms of their tip radii, edge angles and blade profiles. Hooke, referenced above in [2], had also applied his magnifying glass to making observations about the sharpness, or more accurately, the dullness of a 17<sup>th</sup> century razor blade. McCarthy *et al.* employed a finite element description and ABAQUS to develop a “blade sharpness index”. To illustrate further connection with hardness, there are the two reports: first, by Akona, Reis and Ulm [401] on scratching materials ranging in hardness from butter to steel; and secondly, by Keryvin, Crosnier, Laniel, Hoang and Sangleboeuf [402] on scratching a ZrCuAlNi bulk metallic glass. The results of the latter report may be related to hardness and plastic flow measurements obtained on a related material by Ye, Chu, Chen, Wang and Yang [403].

Hakiri, Matsuda and Sakia [404] have applied the optical indentation microscopy technique [73] to report *in-situ* observations of Berkovich-indented contact areas of thin film/substrate composites and modifications of sinking-in or piling-up behaviors in association with hardness and elastic modulus determinations. Continuous loading curve results were obtained for sol-gel derived MeSiO<sub>3/2</sub> film put onto a number of polymer and glass substrate materials. The ISE has been investigated in single crystal copper films by Zong and Soboyejo [405] while MD simulations of single and polycrystal copper films on rigid or single crystal aluminum substrates have been investigated by Bolesta and Fomin [406]; see Fig. 29 and reference [307]. Guisbiers, Herth, Buchaillot and Pardoën [407] investigated the nanoindentation hardness of isolated thin films of tantalum in association with fracture toughness and Young’s modulus determinations. The hardness followed the H-P dependence given above in Eq. (17). Wang, Hu and Shao have reported on surface roughness and internal stress aspects of the nanoindentation hardness of boron-doped polysilicon material [408]. Son, Yoon and Lee have correlated hardness, wear resistance and corrosion resistance of iron-alloy powder consolidated materials [409]. Quantitative hardness results are reported for measurements made by Kauffman, Ji, Arsian and Arzt [410] on a nanocrystalline titanium nitride/silicon nitride coating.

For purpose of relating to polymer coating applications, Spinks, Brown and Liu have performed spherical indentation testing of polystyrene material at temperatures though the glass transition temperature and reported glassy and rubbery modulus values [411]. The measurements relate to another report by Dinelli, Ricci, Srolli, Baschieri, Pingue, Puttaswamy and Kingshott in which indentation versus time curves were determined for thin surface layers so as to relate to the issue of a reduction in glass transition temperature because of the free surface [412]. Gacoin, Fretigny, Chateauminois, Perriot and Barthel [413] also determined hardness test results for an elastic substrate coated acrylate polymer film in the glass transition zone. The viscoelastic moduli were found to be sensitive to hydrostatic pressure. Bundschuh, Kraft, Arsian, Gliemann, Weidler and Woell [414] have reported hardness and Young’s modulus values, in the latter case achieving a value of 9.3 GPa approaching the theoretical value of ~10 GPa or higher, for an epitaxially deposited, intrinsically porous, metal-organic framework material designated as HKUST-1.

## 7. SUMMARY

A review has been presented of hardness and hardness testing results compiled on many different materials and over a very large range in indenter tip dimensions and applied loads. The indenter dimensions have ranged from those for the atomic-scale sharpness of tungsten field emission tips to millimeter-scale spheres, thus corresponding to a range in scale from nano-to-macro-indentation hardness testing. The applied loads have ranged over a scale from hundredths of micro-Newtons to kilo-Newtons. The structural states of the different materials tested have varied between the limits of either being essentially perfect crystals to being amorphous materials and each type of material tested in bulk or thin film condition. Emphasis has been given to the important use and interpretation of continuous indentation loading curves obtained with a spherical indenter tip, particularly as naturally occurs for the rounded tip loading in nanoindentation hardness tests. Metrological aspects of the subject have been discussed. On such a combined basis, the elastic, plastic and cracking aspects of actual hardness results or simulated results have been described for conventional single crystal, polycrystal, nanopolycrystal, and polyphase composites, and encompassing all types of atomic or molecular bonding.
